PROCEEDINGS

of the

Naples Pain Conference

Research and Therapy for Human and Animal Suffering

MAY 16th - 19 , 2010

*N*aples **P**ain **C**onference (*N*PC):

Research and Therapy for human and animal suffering

MAY 16th - 19th, 2010

"To discuss and present the latest developments in Pain and Therapeutics"

Venue: Centro Congressi dell'Ateneo Federico II,
via Partenope 36 - 80131 - NAPOLI, IT

WELCOME TO A MULTIDISCIPLINARY PAIN CONGRESS:

We are far from a full understanding of pain and analgesia.
All of the human pain treatments are also in the domain of veterinary medicine, substantiating shared pain mechanisms by animals.
The quality and degree of suffering change with the stimulus, the individual, and with states of arousal and affect. These factors in turn alter pain control mechanisms.
In spite of a million years of humankind experience, and the developments in medicine, significant progress with pain knowledge is quite recent. Significant developments from the 1960s include the synthesis of new analgesic molecules and the Gate Control theory of pain, the discovery of the opiate receptor system in the 1970s and the cyclooxygenase discovery in the 1980s. More recent discoveries include evidence of spinal plasticity, of windup mechanisms that can prolong or enhance pain, and the therapeutic value of preemptive and multimodal analgesia. In spite of this progress most pain medications also cause a number of unwanted side effects.
Pain is a huge scientific and social issue raising ethical and economical problems. The Aim of this Conference is to update and share the latest developments regarding Pain mechanisms and therapeutics among basic scientists, physicians, and veterinarians.

On behalf of the scientific and organizing committees, I am honoured to invite you to join the *N*aples **P**ain **C**onference (*N*PC): *Research and Therapy for human and animal suffering.*

Giancarlo Vesce, *NPC President*

CULTURAL HAPPENING

THE EXPRESSION OF PAIN IN ART

Sunday May 16th 2010, 6 p.m.
at the *"Quadreria"* of the Pio Monte della Misericordia
Naples, Via dei Tribunali 253

18.00 - 18.10
WELCOME TO NAPOLI
Prof. Giancarlo Vesce, NPC President

18.10 - 18.20
The "PIO MONTE DELLA MISERICORDIA"
Dr. Gian Paolo Leonetti di Santo Janni,
Soprintendente al Pio Monte della Misericordia

18.20 - 18.30
MESSAGE from His Eminence the Cardinal Crescenzio Sepe,
Archbishop of Naples

18.30 - 18.40
NOSTRA SIGNORA DELLA MISERICORDIA
Dott.ssa Maria Grazia Leonetti Rodinò di Miglione,
former "Governatore al Patrimonio" of the Pio Monte della Misericordia

18.40 - 18.50
GESUALDO DA VENOSA
"Musicorum Princeps, Doloris Princeps"
Kathy Toma, painter, co-author of the book
"GESUALDO DA VENOSA - FASTI DIMENTICATI
DI UN PRINCIPE DEL RINASCIMENTO" 2009

18.50 - 19.00
ANIMAL PAIN IN ANCIENT CHRISTIAN POETRY
Prof. Antonio V. Nazzaro, professor of Ancient Christian Poetry,
former Dean of the Faculty of Humanities at the University of Naples Federico II

Strictly personal invitation to obtain by Pio Monte della Misericordia
Invito strettamente personale da richiedere al Pio Monte della Misericordia

Pre Congress day

ANIMAL PAIN IN LATIN CHRISTIAN POETRY
Antonio V. Nazzaro

Il Cardinale Crescenzio Sepe
Arcivescovo Metropolita di Napoli

Prot. N. 04/10R33

Napoli, 23 aprile 2010

Illustre Preside,

riscontro la Sua pregiata lettera, pervenutami nei giorni scorsi, con la quale mi ha invitato al Congresso internazionale "*Naples Pain Conference*", che si svolgerà dal 16 al 19 maggio prossimi, sul delicato tema del trattamento del dolore e della sofferenza dell'uomo e degli animali.

La ringrazio del cortese e gradito invito, che volentieri avrei accolto, in segno di vicinanza e di sostegno.

Mi premuro comunicarLe che, per la presenza, nelle date indicate, di pregressi ed improcrastinabili impegni, non mi è possibile intervenire, come avrei voluto.

Desidero, in ogni modo, formulare sinceri auguri per un'ottima riuscita dell'intero Congresso e della manifestazione al Pio Monte della Misericordia.

L'attenzione al dolore e alla sofferenza è quanto mai urgente ed è segno di autentica umanità e civiltà.

%

Illustre Signore
Prof. **Luigi ZICARELLI**
Preside Facoltà di Medicina Veterinaria
Università degli Studi di Napoli Federico II
Via Federico Delpino, 1
80137 NAPOLI

Il Cardinale Crescenzio Sepe
Arcivescovo Metropolita di Napoli

Le malattie, infatti, colpiscono uomini ed animali, che hanno delle naturali reazioni ad esse, che si esprimono proprio nei sentimenti del dolore e della sofferenza.

È consigliabile, pertanto, che si tenga sempre presenti queste realtà, mostrando empatia e partecipazione e sforzandosi di dare sollievo attraverso la condivisione e le opportune terapie.

Esorto tutti ad avere a cuore questo importante tema, prestando costante attenzione ai soggetti coinvolti, sapendo loro tendere una mano che offra sollievo.

Assicuro la mia vicinanza ed il mio sostegno, incoraggiando a proseguire sempre in questo importante e significativo impegno.

L'occasione mi è gradita per inviare a Lei, al Prof. Vesce, agli illustri relatori e a quanti interverranno al Congresso provenendo da ogni parte del mondo, distinti saluti ed auguri.

+ C. Card. Sepe
Arciv.

Il Cardinale Crescenzio Sepe
Arcivescovo Metropolita di Napoli

Prot. Nr. 04/10R33

Naples, April 23rd 2010

Distinguished Dean,

few days ago I received Your letter inviting me to the International Meeting "Naples Pain Conference" taking place in Naples from May 16th to 19th and dealing with the sensitive subject of pain treatment in human beings and animals.

I really thank You for this kind and welcomed invitation that with pleasure I would have accepted as a sign of my support and closeness.

Unfortunately, I must tell you that because of previous and irrevocable engagement I won't be able to take part to it, even if I would.

But I really want to express my best wishes for a full success of the whole Congress and the event at Pio Monte della Misericordia.

Focusing the attention on pain and suffering is extremely urgent and it represents a sign of true humanity and civility.

Diseases affect human beings and animals who show natural reactions to them, expressed namely in the feelings of pain and suffering.

It is thus necessary to keep in mind this and pay constant attention to the sufferings of the subject involved, being able to hold them out a hand and give them relief.

Urging you always to pursue this important and significant effort, I ensure you my closeness and support.

I seize this opportunity to express my best regards and wishes to you, to Prof. Vesce and to the distinguished speakers and those who will attend the Meeting from all over the world.

† C. Card. Sepe

Crescenzio Cardinal Sepe
Archbishop of Naples

"... O miei cari sospiri
Miei graditi martiri..."

GESUALDO DA VENOSA : «Musicorum Princeps, Doloris Princeps »

Kathy Toma

For the opening of this congress devoted to Pain one could not imagine or dream of a more perfect place to evoke the remarkable individual, Carlo Gesualdo, Prince de Venosa, as it was his own beloved uncle, the cardinal, then archbishop of Naples, Alfonso Gesualdo, who was behind the founding of this venerable institution. The figure of the great composer of madrigals, of the "musician-murderer," best known for the dismal tragedy of killing his gorgeous wife and her lover, has been shrouded in a sulfurous cloud that still contains mysteries (1). Almost forgotten for centuries, the art of the "musician-murderer" was virtually rediscovered by Stravinsky in mid-twentieth century and has continued to inspire, today more than ever, writers, poets, cinematographers, composers, musicians, screen writers and, even, psychoanalysts. From Huxley to Schnittke, Herling, Schifano, Iudica, Werner Herzog, Dominique Fernandez, Krausser, Francesco D'Avalos, Sermonti-Francesconi, Tracanna-Guarino, Sciarrino, …and Bernardo Bertolucci, (the list is even longer…)

Since then, the interest aroused by his modernity has steadily grown among those sensitive beings who, after the horrors of world wars, genocides and the Holocaust, have seen ideologies crumble, the birth of existentialism and the awareness of the absurd.

Like Giordano Bruno and Caravaggio, the Prince of Venosa belongs to the cursed breed of artists, to the visionaries, whose thought travels at supersonic speeds in a world not ready to welcome them, preferring to burn them on the pyre of intolerance. The dichotomy between their individuality and their place in society in a particularly oppressive age, when Counter-reform and Inquisition reigned, could only have been a source of heartbreak. The experience of physical and psychological pain in a world that rejects them will carry them, through the catharsis of their art, to the realm of the sublime.

The Prince de Venosa is the Prince of Pain. Very early, at the age of seven, he was to lose his mother, Geronima Borromée –sister of the future saint - and the niece of Pius IV. As well, from very young his health was fragile: he had asthma (the malady "del castrone"); later he would suffer for a long time from an unhealed fractured leg after falling from a horse; but, more than that, he would be sickened for life, poisoned by a horrible potion prepared by a witch at the request of a concubine who refused to be rejected. (2) The two women would end up in the dungeons of the Gesualdo's château after their trial.

Psychological pain would be his companion throughout his life.

Betrayed once, Gesualdo will be so doubly by his destiny which obligates him to become, a first time at eighteen years old, head of the family at the death of his older brother, Luigi, in the year 1584: a terrible year for him marked by two other bereavements – the death of his beloved grandfather, Luigi, who bequeathed to the family the title of Prince, and that of his uncle, Charles Borromée.

Gesualdo, far from wanting to devote his life to a "career as prince," thought only of assuaging his singular passion: music.

The second betrayal, that of his wife Maria D'Avalos whom he wed in 1586, will feed all the gossips of the time causing him to become the laughing-stock of the entire city of Naples. He will have to face the horror of the code of honor then in force. And so the beautiful Maria D'Avalos and her lover, the Duke Fabrizio Carafa D'Andria, caught in the act, will be killed in the palace of San Severo in Naples the night of the 16th of October 1590 by Carlo Gesualdo who fled Naples the same night and sought refuge in his château in Gesualdo.

This terrible tragedy, this moment of madness when everything in his life turned upside-down at the

age of twenty-four, is only a prelude to a long series of misfortunes that will batter him relentlessly like a curse (3). In 1600 Alfonsino died, the second son born of his second wife, Leonora d'Este, whom he wed in Ferrara in 1594, quite probably poisoned, he as well, in Gesualdo by the same witch. Carlo allows himself to die of despair, the 8th of September 1613, after writing his will, following the tragic death of Emanuel, his only son with Maria d'Avalos, fallen from a horse during a hunt, the 20th of August, at the age of twenty-six.

"Io Tacero, ma nel silenzio mio
Le lacrime e i sospiri diranno i miei martiri..."

Even if the gesualdien tears and sighs are part of the "saturnine" tradition, including the celebrated *Mélancholie* by Dürer, as well as the *Lamentations de Saint Pierre* by Roland de Lassus, or *flow my tears* by Dowland or the *Lamento d'Arianne*, the gesualdien pain is distinct from all the others. Its accents cannot be coded, allying archaisms and modernism, pushing to the limits the potential of counterpoint and dissonance, showing strong affinities with certain painters, as with El Greco or Caravaggio, in their treatment of light, color or the increase or decrease in perspective.
(We may one day discover links between the Gesualdo family and Caravaggio not yet explored, as a painting by Caravaggio (a *Salvatore*) is mentioned in the inventory of the Château Gesualdo).
Pontormo, by his science of color, the richness of his tones and the exceptional silence that envelopes his floating world, Rosso Fiorentino whose fantastic purplish palette is like a sigh exhaled from the *Responsoria* and Cosmè Tura belong to the same dream-like universe.
Who knows if Carlo had the chance to see his extraordinary painted panels from the organ of the Ferrara Cathedral where the Princess is pictured as contorted by anguish? With a marvelous gesturing of her hands she captures a strange light that also illuminates a portion of her face where through her open mouth a cry escapes from between her teeth. The archaisms and the modernism of Cosmè, the mystery and depth, the mixing of sacred and profane are of the same order: the oxymoron's alchemy...

"…Enfer ou Ciel, qu'importe!" -La musique pour ne pas mourir-

In Carlo's last piece of sacred music, the *Responsoria et Alia ad Officium Hebdomadae Santae Spectantia* ,(1611) probably his spiritual and artistic testament, we are surprised by the process of his identifying with the passion of Christ. Through the drama of God's son, abandoned and betrayed by all, is revealed the profound solitude of man/Carlo lambasted by pain who seeks answers to his questions, perhaps some alleviation of his interminable suffering.
In the last two Books of the Madrigals (V and VI), a contemporary publication, where the form "a sei voci" (for six voices) dominates, the same existential misery resonates.
There love is a corollary of death: *Madrigaux* et *Répons* intermingle, no border separates sacred music from profane. The eroticism of religion is counterpart to the mysticism of love in a brilliant oxymoron. The religion of love travels between sacred and profane.
Life charted the fate of the Prince: his art is the only reply/question he can offer as it rises up with a terrible radiance from the disturbing chiaroscuro of his soul, amidst a silence yet filled with voices:
"*...che nel silenzio ancor son voci e prieghi"*
When we hear: *"mercè grido, piangendo/ma chi m'ascolta?"* The expression of man's existential solitude reaches the infinite as in the despairing narrative of Christ in the *Responsori: "Posuerunt me in deserto solitudinis"* and especially when the cry arises *"quid me dereliquisti ?"*. Questions without answers.
The key word, *"tradidit",* repeated insistently, expresses supreme betrayal, while *"flagellatum"* beats on the martyred flesh of the Grand d'Espagne, the Prince de Venosa, known to have submitted to masochistic sessions of flagellation, reported by Michele Giustiniani (4) and by Ferrante della Marra (5) and for whom the famous doctor Tommaso Campanella (6) provided the diagnosis.

The manic tones of the *"Io moro"* reach the cosmic shores of unfamiliar regions. The music becomes prayer, the interpellation is universal, the question crosses space and time to reach us, and beyond, and remains unanswered, eternally unresolved:
"O vos omnes qui transitis per viam, attendite et videte si est dolor similis sicut dolor meus", an unending quest "pietas" in this piece already put to music by Carlo in the *Sacrae Cantiones* of 1603 that ends with the words "dolor meus"- presence of my suffering self – of an extreme softness, like a puff of air, like the last sigh that disappears into eternity.

The writer, in attributing to flagellation the virtue of curing intestinal obstructions, adduces in proof of his assertion the case of Gesualdo: *"Princeps Venusia musica clarissimus nostro tempore cacare non poterat; nisi verberatus a servo ad id adscito",* in chapter *"Monstruosa Cura"(The Prince of Venosa, one of the best musicians of this age, was unable to go to the stool without having been previously flogged by a valet kept expressly for the purpose).*

ANIMAL PAIN IN LATIN CHRISTIAN POETRY

Antonio V. Nazzaro

1. Pain is a typical condition in men and animals, our minor brothers. Over the centuries scientists have enormously contributed to alleviate pain both in men and animals and to defeat recurrent forms of lethal epidemics, with the result to decrease death rate mainly in the wealthier regions. Unfortunately nothing can be done to defeat totally recurrent and devastating forms of illness. Through the centuries the theme of pain both in men and animals has been widely dealt with in many philosophical and theological speculations, in literature, poetry and all forms of art all over the world.

Many thinkers and philosophers have questioned the existence of pain in the world, at times seen as a means of redemption by Christian theologians. Poets, painters and musicians have portrayed both individual and cosmic pain in immortal masterpieces.

In the Bible all animals, creatures of the Almighty, show signs of His divinity and share men's destiny on earth.

Qoèlet says: « Also to them is the event of the sons of man, and the event of the brute; one event befalls them: as is the death of the one, so also the death of the other, ant there is one breath to all: and what has the man more than the brute? Nothing; for all is vanity»(3, 19)

According to the Apostle Paul animals as well as men take part to redemption and spiritual freedom, having both experienced pain and labor in delivery(*Rom* 8, 22).

In their writings Christian writers and poets were influenced by pagan poetry and inspired by the Bible.

2. As to my paper subject, I've to mention Severus Sanctus Endelechius, friend of Paulinus Nolanus (IV-V century), who is the author of *De mortibus boum* (*The Death of the Cattle*). This short poem in 33 asclepiadean stanzas is closely modelled on Virgil's Eclogue I and Georgics III (474- 566).

In these verses the Latin poet describes a serious plague infection among oxen in the region of Norico. He clearly had in mind *De rerum natura* 6, 1136-1284 of Lucrece, who deals with pestilence in Athen in 430 b. C. In both poems pestilence causes a very high mortality rate and in reading their lines we almost forget that the virgilians victims are animals. For he describes the event with such pathos, suffering and emotion for the oxen's death caused by air and water pollution.

The poem *De mortibus boum* by Endelechius, considered as a poem of religious propaganda, tells of a plague, which devastates vast areas of central and western Europe, finally reaching Gaul where the poem is set. While the shepherd Buculus is complaining with Aegon about plague that killed all his animals, comes on stage Tityrus who tells his cattle were saved by having the sign of the cross made on their foreheads. Then Buculus and Aegon are converted to Christianity. At the end of the poem three shepherds leave the pastoral landscape and set off for the city to go to church.

3. Now i'll read to you my translation of latin christian poem about the Death of the Cattle:

<*Aegon*> Why do you miserably sigh, Buculus, wandering alone with your sad eyes downcast? Why do copious tears stream down your cheeks? Please, allow your friend to know this.

< *Buculus*> Aegon, I beg you, let me keep my painful emotions in a deep silence, for he who reveals his troubles opens the wound; on the contrary, he who stifles them in silence heals them.

<*Aegon*> The opposite of what you say is true; your claim is false. For a burden shared becomes less heavy, but what is covered over boils up more fiercely. Talking helps to relieve pains.

<*Buculus*> You are aware, Aegon, what a large flock I had, and that my cattle grazed beside every river: they filled even the hollow valleys, the fields and the mountain ridges. Now all hope based on my wealth has vanished and what my long work produced throughout all my life lost in a two days' time. So swift is the running toward troubles!

<*Aegon*> This painful pestilence is now said to be spreading. Not long ago it caused the Pannonians, Illyrians and Belgians terrible destruction, and now it is attacking us, too, in its foul progress. But you, who know how to drive out harmful pestilence with medicinal juices, why do you not forestall the danger you fear by applying your healing hands?

<*Buculus*> There are not warning signs of such fear. What the disease attacks it also destroys, it admits no lingering, allows no delay. Thus death anticipates the pestilence. To the farm carts I'd yoked oxen of strong build chosen as carefully as possible. Both of them shared the same thoughts, and their bells tinkled in harmony, both the same age, with the same colour bristles, they were both gentle, both equally strong and they had the same fate, for in mid-course the pair of them collapsed in identical death. I was sowing the emmer deep in the softened earth, the clods were crumbling after the copious rain: the plough moved easily through the furrows, nowhere did the ploughshare stick. The ox on the left, who was tamed in the past summer, collapsed suddenly and fell: at once I unyoked his grieving partner, nor fearing further misfortune now. But faster than one could say, death seized him although he had always been healthy before. Now he, jerking his flanks with long fits, bent his head worn out.

<*Aegon*> I feel anguish, and torment, sorrow and grief, for my heart is shattered by your losses, as if they were my own; and yet I believe your herd is now safe?

<*Buculus*> O dear! I'm going where I must expect something far worse. For it would be some confort in my trouble, if only a little, if a following litter had given to me what this plague had taken away. But, who would have believed the litter were killed at the same time? I myself saw the pregnant cow headlong: I saw two lives destroyed in the one body. Here a heifer, refusing the spring water and neglecting the grass, wanders on wobbly legs, but she cannot escape infection, for she falls heavily, tripping on death chains. Over there is a calf, who just now frolicking around had outlined fanciful caprioles, goes to suckle his mother; but soon he sucks the infection from the diseased udder. When his mother, wounded by this sorrowful pain, saw her calf closing his eyes, she repeatedly bellowing and pitifully groaning, collapsed, longing for death. Then as if she feared that thirst might choke the parched throat, while she lay there dying too, she moved her udder to her calf who was already dead. Love remains strong even after death. There is the bull, husband and father of the healthy herd, with his strong neck and broad forehead; while he
was happy and very proud of himself, he falled heavily in the grassy meadow. As many are falling leaves of which the wood is stripped when lashed by the icy north wind, as thickly as the snowflakes flutter in a blizzard, so numerous are the cattle which have died. Now the whole ground is covered with carcases, their bodies swell with the bloated bellies, their eyes are white with livid patches, their legs stiff with rigid hoof. Already flocks of baleful and grim birds are hovering; already packs of dogs press round to tear the bowels and feed on them. Alas, why not on mine also?

<*Aegon*> Why, I ask you, why the death's grim fate is so inconstant, that it passes some over, but striks others? Look at Tityrus, happily driving his healthy flick.

<*Buculus*> Yes, I see him now. Come tell us, Tityrus, which God has saved you from these troubles, so that the plague that ravaged your neighbours' flocks has not affected yours at all?

<*Tityrus*> The sign wich is said to represent the cross of God who alone is worshipped in the big cities, Christ, the glory of the eternal God, whose only Son he is, this sign, made over the forheads, brought my cattle's sure salvation, and for thi reason this powerful God is now truly hailed as our Saviour. The raging plague at once fled from the herd, the pestilence lost its strength. But if you wish to pray to this God, it is enough to believe. Faith alone makes your prayer effective. His altar is not dripping with blood, the disease has drived off by no slaughter, but simplicity and purity of mind obtain the desired rewards.

<*Buculus*> If you sure about this, Tityrus, I will without delay begin to perform the rites of the true faith, I will gladly flee from the old error, for it is deceptive and illusory.

<*Tityrus*> Already I am keen to hurry and visit the temple of almighty God; come, Buculus, let us go together – it is not far – and acknowledge Christ's divinity.

<*Aegon*> Please, join me to your happy plan. For how could I doubt that mankind, too, will for ever benefit from this sign which overcame the powerful plague?

To sum up, this poem clearly shows the Christian poets are very sympathetic to animal's pain. Thank you!

Conference Opening

John Bonica memorial lecture:

“THE PAST, PRESENT, AND FUTURE STANDARDS FOR MANAGEMENT OF PAIN”

Charles E. Short DVM, PhD, DACVA, DECVA

Testimonial: *John Bonica at Naples* – Prof. Alberto del Genio M.D.

THE PAST, PRESENT, AND FUTURE STANDARDS FOR MANAGEMENT OF PAIN

Charles E. Short, DVM, PhD, DACVA, DECVA

Cornell University, College of Veterinary Medicine, Department of Clinical Sciences, Ithaca, NY USA - CKShort@aol.com

Even before there was a standard for the management of pain, it was recognized that pain was associated with natural conditions, trauma, and disease. The concept of pain involving the nerves and brain can be traced back to 566-260 B.C. in ancient Greece. It was established in ancient Rome that inflammation is a phenomenon of redness, swelling, heat, and pain. Galen (131-200 A.D.) defined three classes of nerves: soft nerves for sensory function, hard nerves for motor function, and "third type" for pain sensation.

The ancient standard for management of pain included combinations made from the poppy, mandragora, hemp, or henbane as a potion or combined with wine. A major task of Jesus Christ was to heal the sick and banish pain and suffering in the Judeo-Hebraic civilization.

The use of morphine and local anesthetics were the standard therapies with or without general anesthetics including diethyl ether or chloroform as recently as 50 years ago. In many conditions, the fear of uncontrolled pain was worse than the concern for the outcome of the health problem.

Has there been progress toward an acceptable present standard for management of pain? Where are we now?

The management of pain is a major medical challenge for the relief of suffering in animal and human patients. It is of global concern likely to effect up to 45% of the human population at some time and countless animals both domestic and wild. In 1990, John Bonica, MD, reported the incidence of unrelieved pain in acute and chronic conditions varied from 30-100% depending on the condition and the therapy provided. The percent of the population requiring therapy for moderate-to-severe pain was remarkable. The incidence of unrelieved moderate-to-severe pain in animals was not available. Considering the available medications and the nonspeaking animal patient and the lack of emphasis on treating animal pain, it should be obvious at that time the need for major improvement was highly significant.

Fortunately during the last 20 years, much progress has been made. Now new and better analgesics are available. The scientific base for concepts of biochemical and neurologic mechanisms of pain has been much improved. Studies in the pharmacokinetics of our medications coupled with better diagnostic and monitoring capabilities now enhance improved patient care.

Our attitude toward providing pain management also changed remarkably. Pain became a vital sign in our patient evaluations regardless of presenting symptoms or treatment requirements. Effective pain management became a standard of good medical practice in both medical and veterinary medical hospitals. Educational programs within our colleges and universities coupled with advanced scientific research expanded the new knowledge to the medical professions. The efforts of the pharmaceutical industry and regulatory agencies provided new therapies for safer and more effective treatments.

All the national and international pain organizations, including the International Association for the Study of Pain, actively promoted a standard of pain practice. The American Animal Hospital Association adopted a required standard for all accredited hospitals in 2003. This was a major milestone in improving pain management in companion animals. Pain is a multispecies concern; but when one or more organizations require a standard of management, other improvements will follow.

Having a standard for acute and chronic pain management would be of little value if modern analgesics were not available. The major emphasis on new nonsteroidal analgesics has been crucial to improving chronic pain management and a major factor in post-surgical pain for orthopedic patients.

Morphine continues to be an effective analgesic with many indications. It is widely used in man and

animals especially where cost of medication is of major concern. Other opioid agonists such as hydromorphone and members of the fentanyl family have become widely used analgesics with multiple dose methods (oral, injectable including constant rate infusion and transdermal).
Buprenorphine and butorphanol are being used more frequently in some patients than the mu-agonist opioids. It is not unusual for either of these to be combined with an α_2 agonist for effective pain management.
New opioids and treatment modalities have improved comfort in the dental, surgical, and cancer patients. Fortunately, other medications including α_2 agonists and anticonvulsants may be used to supplement other treatments in difficult pain syndromes.
Dexmedetomidine used alone or in combination has been found to be effective in select animal and human patients. Both xylazine and detomidine became major analgesics in the horse and can also be used in cattle.
Patients with neuropathetic pain do not always get needed relief with opioids alone. Gabapentin has shown great promise in some of these patients, especially as a supplement to more traditional pain therapy.
Pain management can now be individualized for each patient and the presenting condition. This is true in medicine and in veterinary medicine. In acute pain, management usually extends until the tissues involved heal. In contrast, treatment of chronic pain extends for long duration especially in cases of cancer or severe arthritis.
We have learned pain management should accompany all surgical procedures. Gone are the years when it was acceptable to consider a stormy post-surgical recovery was just a bad anesthetic response. Isoflurane or sevoflurane recoveries are very rapid. It has become evident that concurrent pain management is the only way to assure comfort in almost all patients as they arouse from the anesthetic state. We have learned to balance the use of analgesics and anesthetics for a high standard of management of the surgical patient.
The populations of both people and many animals now have an extended life span. As a result, chronic conditions are major medical issues. The treatment of cancer is not limited to surgery, chemotherapy, or radiation. It must also include patient comfort. The primary difference between people and animals in *severe, uncomfortable* cancer pain is that in animals an overdose of anesthetic is acceptable when there is no longer hope for recovery. Sometime that is the only humane action left as a standard of animal care.
Pain scoring is much more complicated in animals and in infants. It is difficult to determine the level of pain by observation in many cases. As a result, the choice of medication and the dosage often varies and in many cases appears inaccurate. Fortunately, biochemical markers and advanced techniques to monitor the brain and nervous system have provided much needed data to help the professions more accurately treat with a safe and effective protocol.
We now can evaluate new medications based on its uptake, distribution, and elimination; the changes in EEG and other neurologic indicators with and without noxious stimulation; any changes in stress hormones; the hemodynamics; and alterations in behavioral pattern. Studies of these parameters have already been made during research and development. Similar studies of drug combinations are necessary due to the interactions in multimodial pain medication.
Now we are at a crossroads in the management of pain. In many practices and hospitals, it is practiced at a *high standard providing comfort to both acute and chronic patients.* However, in many others, the standard of pain management is unacceptable. Why? There is a long list of reasons. The list includes lack of effective medications in many parts of the world, economics, lack of knowledge, customs, and in some cases a lack of concern. What is next?
Will slow release injectable opioids join the list of slow-release oral opioids? Extensive studies of slow release injectable sufentanil showed it is possible. Will slow-release NSAIDs be significant in the future? Two long-lasting NSAIDs (mavacoxib and robenacoxib) have been developed. The promise of a better understanding of pain management options will contribute to a higher standard in pain management.

This has especially been beneficial in canine osteoarthritis when several predominantly COX_2 NSAIDs have been approved along with one dual channel NSAID. The advances for feline chronic pain have progressed at a much slower pace. NSAIDs continue to be a major medication in equine orthopedic pain.

NSAID usage in people continues to be a major factor in inflammatory pain despite the removal from the market of some effective medication due to adverse side effects including cardiovascular concerns.

The ideal standard of pain management for the future would be global in scope. It would follow the principles of clinical pain management so well practiced and taught by Dr. John Bonica. The core for this future standard will be knowledge and available medications worldwide. It will take cooperative efforts by industry, government, academia, and the patient care providers. The development of new analgesics is important, but likewise is the availability of inexpensive analgesics to economically poor countries. It is important to learn through research the biochemical mechanisms and the influence of new medications on specific nerve pathways. But it is also important to teach the medical care providers how to practice practical and effective pain management for their patients.

The selection of medications and the route of administration is not the same for all creatures great and small. The combination of medications for the surgical patient is not the same for the patient with severe osteoarthritis. Each patient, however, has the right to pain management and we have an obligation to provide comfort.

We have the opportunity by working together as part of the international medical community for the relief of pain and suffering to make a difference for countess patients. This objective is truly a part of the one medicine concept to serve all creatures great and small including the human race. Our efforts will be a tribute to the vision and works of Dr. Bonica, to whom we are so indebted for his leadership.

"BRAIN REGIONS AND NEUROTRANSMITTERS MEDIATING OPIOID INDUCED SLEEP DISRUPTION"

Helen A. Baghdoyan, University of Michigan

- Support and Conflicts of Interest: This work was supported by National Institutes of Health Grants MH45361, HL57120, and HL65272, and by the Department of Anesthesiology, University of Michigan. There are no conflicts of interest.
- Background and Clinical Relevance: Sleep states, anesthetic states, and mental states are modulated by overlapping brain regions and neurotransmitters. This talk will focus on the sleep- and pain-related actions of GABA and adenosine in the pontine reticular formation.
- Background and Clinical Relevance: Opioids disrupt sleep; pain disrupts sleep, and sleep disruption worsens pain.
- Background and Clinical Relevance: GABAergic transmission in the pontine reticular formation promotes wakefulness: Most drugs that are used to produced sleep, sedation, or general anesthesia increase transmission at GABA-A receptors. However, GABAergic transmission in the pontine reticular formation actually increases wakefulness. This finding emphasizes the need to understand drug effects on a brain-region-by-brain-region basis.
- Results and Interpretation: Morphine acting at mu-opioid receptors in the pontine reticular formation decreases endogenous GABA levels and disrupts sleep. Thus, the pontine reticular formation may be one site where morphine acts to cause disturbed sleep.
- Background and Clinical Relevance: Adenosine is a neuromodulator that promotes sleep by its actions at the level of the pontine reticular formation and the basal forebrain. Adenosine also contributes to pain management.
- Results and Interpretation: Morphine and fentanyl decrease levels of adenosine in the pontine reticular formation and in the substania innominata region of the basal forebrain. These data suggest that sleep disruption caused by opioids may be mediated by decreasing the sleep-promoting effects of adenosine.
- Background and Clinical Relevance: Buprenophine is an opioid that acts as a partial agonist at mu-opioid-receptors and an antagonist at kappa and delta opioid receptors. Buprenorphine is used effectively as an analgesic. The effects of buprenophine on sleep an on adenosine levels in regions of the brain that regulate sleep have not been reported.
- Results and Interpretation: This presentation will report new data showing that in rat 1) an antinociceptive dose of buprenorphine causes significant sleep disruption; 2) co-administration of the benzodiazepine receptor agonist eszopiclone reverses the sleep disruption caused by buprenophine; and 3) buprenophine decreases levels of adenosine in the substantia innominata region of the basal forebrain. These findings support the interpretation that opioid-induced disruption of sleep is caused, at least in part, by decreased adenosine levels in the basal forebrain. These data also suggest that eszopiclone may provide adjunctive therapy for sleep disruption caused by buprenophine.
- Future Directions: Understanding the brain regions and neurotransmitter systems by which pharmacological treatments for pain disrupt sleep will provide opportunities to develop effective countermeasures to improve patient care.

GATING OF SENSORY INFLOW THROUGH NOCICEPTIVE PATHWAYS DURING SLEEP

Peter J. Soja

Faculty of Pharmaceutical Sciences, The University of British Columbia, Vancouver, BC Canada V6T 1Z3 E: drpsoja@interchange.ubc.ca

It is well known that humans spend approximately one-third of their lives (~25 years) in the states of non-rapid-eye-movement (non-REM) and REM sleep. In these states, sensory and pain perceptions are markedly diminished when compared to the awake state [1-5]. Unfortunately, the neural mechanisms and pathways that are responsible for the reduction in pain perception during sleep states remain a mystery and consequently represent a prime untapped reservoir of naturally occurring targets that future research may ultimately prove to be critical for pain control and improved sleep.

The spinothalamic tract (STT) and related trigemino-thalamic tract (TGT) are the main ascending somatosensory pathways in the central nervous system that convey nociceptive information leading to the experience of pain. Data from *in vivo* electrophysiological studies of how nociceptive information is transmitted through these sensory channels and then modulated by higher brain centers remain by and large confounded due to the use of invasive surgery, anesthetic drugs, and paralytic agents [6-11]. Hence, despite the extensive literature, relating data derived from these studies on how the natural sleeping brain regulates itself with findings on how the anesthetized brain and spinal cord process incoming nociceptive signals is, at best, problematic.

Albeit challenging and time-consuming, appropriately designed neurophysiological recording studies in intact behaving animals offer a powerful way to delineate the mechanisms and neural networks underlying the interactions between the states of sleep and pain. Over the past four decades, sporadic attempts have been made to assess how the brain modulates prethalamic sensory inflow during sleep and wakefulness. Understanding this process is a prerequisite for understanding how pain affects sleep. The following surveys the current state of knowledge regarding how sleep affects sensory inflow using a "bottom-up" systems approach, beginning at the spinal and trigeminal brainstem levels and with peripheral evoked field potentials followed by an overview of single-unit recording experiments.

Evoked Potential Studies In the late 1960s, pioneering studies utilizing gross evoked potentials conducted by Pompeiano and his colleagues provided seminal evidence that spinal somatosensory neurotransmission is attenuated during naturally occurring sleep [4, 12, 13]. These reports showed that hindlimb nerve-evoked responses recorded from ipsilateral thoracic (T_{12}) ventrolateral quadrants or field potentials recorded in the cat cerebellum were suppressed only during the phasic eye movement events that are characteristic of desynchronized or "active" REM sleep, and not during other states.

Paradoxically, sensory inflow is also enhanced during sleep, particularly REM sleep relative to "drowsy" wakefulness. For example, Favale et al.[14] delivered low-intensity shock stimuli to the subcutaneous tissue of one forelimb of the cat. They reported that the magnitude of peripheral shock-evoked potentials recorded in the thalamus was enhanced by 20–50% when compared to responses recorded during drowsy wakefulness. It was not determined whether this finding represented an increase in the excitability of thalamic neurons, or if it was due to a change in the excitability of STT neurons [14].

We have reported that sensory transmission through classical ascending sensory pathways, including the STT, spinoreticular tract (SRT), and spinomesencephalic tract (SMT), are tonically suppressed during REM sleep [15]. In our study, additional suppression occurred phasically during rapid eye-movements and the other events that are hallmarks of REM sleep. Our findings indicated that the cells of origin contributing to the evoked response in the ventrolateral reticular formation

arose from ascending projection neurons in the contralateral lumbar spinal cord [15]. The pharmacological basis for the REM-sleep-specific suppression and facilitation of prethalamic sensory inflow[1] that was noted in these studies remains unknown.

At the brainstem level, Hernandez-Peon *et al.* [16] reported that field potentials representing the summed activity of numerous neurons, elicited by tactile stimuli applied to facial receptive fields in behaving cats, were dependent on the animals' level of vigilance. In their studies, the orthodromic field potential recorded in the rostral portion of the trigeminal brainstem sensory nuclear complex (TBSNC) was maximal in amplitude during "slow-wave," or non-REM, sleep, but was suppressed during alert wakefulness or REM sleep. On the other hand, Satoh *et al.*[17] reported that tooth-pulp-evoked field potentials recorded in the rostral portion of the TBSNC did not change during wakefulness, non-REM sleep, or REM sleep [17]. We identified a specific area within the rostral TBSNC in which field potentials evoked from the inferior alveolar nerve and from tooth pulp are suppressed *tonically* during REM sleep in a stimulus-intensity-specific manner [18]. Comparable studies have yet to appear that assess neuronal changes during sleep *vs.* wakefulness at the level of the nucleus caudalis, an area of the TBSNC considered to be the trigeminal homologue of the spinal dorsal horn for nociceptive pain transmission [19, 20].

Single Neuron Recording Experiments Individual trigeminal brainstem neurons have also been monitored in unanesthetized, intact, behaving cats [16, 18, 21]. Peripheral-nerve-evoked responses of TGT neurons have also been monitored during the sleep/wake cycle. We discovered that responses evoked by stimulation of the inferior alveolar nerve either increased or decreased during REM sleep when compared to wakefulness; the population mean was not affected [22]. However, when the smaller-diameter fibers of the tooth pulp were stimulated to activate TGT neurons, the tooth-pulp-evoked responses recorded from each cell were markedly suppressed during REM sleep compared to the waking state. These data strongly argue for the presence of a complex gate control mechanism that is engaged specifically during the state of REM sleep, which has features reminiscent of those described over 40 years ago by Melzack and Wall [23]. This REM-sleep-specific "gate" appears to regulate sensory input in a fiber-diameter-specific (or modality-specific) manner.

State-Dependent Excitability Changes of Lumbar Sensory Neurons Relatively few published studies have recorded the activity of dorsal horn sensory neurons during the state of wakefulness. Kishikawa et al. [24] concluded that the air puff-evoked hair-mechanoreceptor responses of unidentified "sensory" neurons in the lumbar dorsal horn *increased* during REM sleep. Kishikawa et al. [24] hypothesized that innocuous sensory inflow via dorsal horn neurons was *disinhibited* by descending systems during REM sleep. An alternative explanation that was not discussed by Kishikawa et al. (1995) is that their recorded interneurons may actually have been premotor *inhibitory* neurons receiving convergent sensory afferent inputs [25]. These neurons may participate in the descending inhibitory pathway to motoneurons that are activated during the state of REM sleep [26] or neural pathways conveying complex excitatory amino acid-mediated drives underlying the myoclonic twitches and jerks that occur during phasic eye movement periods of REM sleep [26-29].

Our own chronic single-unit recording studies have utilized antidromic identification procedures, *in situ*, to examine synaptic transmission through the dorsal spinocerebellar tract (DSCT), a classic sensory pathway conveying proprioceptive and exteroceptive information rostrally to the cerebellum [30, 31] and to prethalamic tectal nuclei [32]. DSCT neurons display moderate ongoing spike activity (~17 spikes/second) during the behavioral state of wakefulness [33]. Hence, proprioceptive and exteroceptive input conveyed to higher brain centers by DSCT neurons is robust during the state of quiet wakefulness. Sensory inflow through the DSCT was found to be consistently and markedly suppressed during the "atonia" of REM sleep when compared with other states such as wakefulness or non-REM sleep. Neurons that contribute to the SRT, one of several consortium pain

pathways studied in acute animal preparations [6, 34], and which are located near DSCT neurons in the lumbar L_3 spinal cord segment also demonstrated REM-sleep-specific depression of their ongoing spike activities [35, 36]. This REM suppression of sensory input was attributed to a process of postsynaptic inhibition based on the following observations: 1) decreased spontaneous spike activity, 2) decreased peripheral-nerve-evoked mono- and polysynaptic responses, and 3) decreased cellular excitatory responses to juxtacellularly applied glutamate [33, 35-40]. Using these three measures of activity, the investigations revealed that the excitability of DSCT neurons, as a distinct, homogeneous population, did not differ dramatically between wakefulness and non-REM sleep. Furthermore, the $GABA_A$ antagonist bicuculline and glycine antagonist strychnine, when applied in amounts sufficient to selectively block inhibition by GABA or glycine, respectively, enhanced the ongoing and glutamate-driven spike activities of DSCT neurons during wakefulness and non-REM sleep. This key finding suggests that GABA- and glycine-mediated inhibitory influences tonically control DSCT neuron excitability during these behavioral states. More importantly, the inhibition of spontaneous and glutamate-driven spike activities of DSCT neurons during REM sleep were also markedly reduced in the presence of bicuculline or strychnine or abolished when both antagonists were co-administered [40]. Further studies using microdialysis probes positioned in the spinal gray matter, where DSCT and SRT neurons are located, revealed that during naturally occurring REM sleep, glutamate, GABA, and glycine levels were markedly increased over basal levels observed during wakefulness, whereas dopamine levels were markedly decreased [41] .

Novel Modulatory Influences during non-REM Sleep. A characteristic hallmark feature of non-REM sleep are the 7–14-Hz spindle oscillations in the EEG which individually last from ~1–1.5 seconds and occur every 3–4 seconds. During non-REM sleep when sleep spindles are present, sensory inflow from the thalamus to the cortical mantle is obliterated [42, 43]. We have recently discovered that certain SRT neurons (~50% of a sample population), but not DSCT neurons [44, 45], present *lower* spontaneous spike rates immediately before or after sleep spindles when compared with spike rates of the same neurons during computer-tagged sleep spindle oscillations of non-REM sleep or wakefulness. It is tempting to speculate from such findings that the *spinal cord* may be the first site in the central nervous system where afferent sensory inflow to the thalamic nuclei is subjected to de-afferentation mechanisms that are activated during non-REM sleep [42, 43] and may even partly explain the reduction in subjective pain sensitivity in humans to certain sensory stimuli during non-REM sleep [1]. Further studies of SRT and STT neurons are sorely needed in order to tease out the responsible cellular mechanisms and neural networks (intersegmental or supraspinal) that are involved during non-REM sleep. Such efforts would provide important new information that may aid in the development of new pain therapies.

Summary and Conclusions: The functional implications of the sleep-related modulation of identified prethalamic sensory tract neurons remain an important, fundamental, and open question. It may now be timely to consider the possibility that sleep serves an unrecognized vital function over one's entire lifetime, namely, to keep somatosensory input including pain in proper check and in a manner appropriate to the organism's behavioral repertoire. From the human perspective, when sleep is postponed due to societal demands or other medical reasons, this exquisite control of sensory processing may be compromised. Future studies directed at bridging these two fields of science hold tremendous promise for providing novel therapeutic strategies for patients suffering from inadequate sleep, chronic pain, or both.

IMMUNE RESPONSE, PAIN AND SLEEP: BRAIN MECHANISMS MEDIATING CYTOKINE EFFECTS ON SLEEP

Luca Imeri, University of Milan Medical School, Milan, Italy

Pain is a hallmark of inflammation. The central nervous system (CNS) senses peripheral infection, subsequent inflammation and immune activation through different mechanisms. For instance, cytokines, such as interleukin-1 (IL-1) and tumor necrosis factor (TNF), whose production is increased in these conditions, enter the CNS through brain areas lacking the blood brain barrier. Cytokines can also activate primary afferent nerves, such as the vagal nerves, which project to the nucleus tractus solitarius in the brainstem, where glutamate release is increased during peripheral inflammation.

Once cytokines are inside the CNS, they stimulate their own production and induce what is known as sickness behavior. Sickness behavior includes reduced intake of food and beverages, reduced interest in the physical and social environments, and altered sleep. Rapid eye movements (REM) sleep is inhibited, while non-REM sleep is increased and fragmented.

The increase in non-REM sleep is mediated, in part, by IL-1, which interacts with specific neuronal circuits and neurotransmitter systems in brain. Interleukin-1, for instance, inhibits the firing rate of wake-active serotonergic neurons in the raphe nuclei. This inhibition is the result of IL-1-induced potentiation of GABA effects on these neurons. But IL-1 increases NREM sleep also because it potentiates serotonin (5-HT) release from axon terminals in the anterior hypothalamus (and adjoining basal forebrain), i.e. in the only brain region where 5-HT is necessary for sleep that naturally follows wakefulness. At this level, 5-HT i) inhibits cortically-projecting cholinergic neurons, which are important for electrocortical arousal, and ii) stimulates IL-1 synthesis, which inhibits wake-active neurons.

Animal studies also show that IL-1 i) inhibits cholinergic neurons in the laterodorsal tegmental nucleus (LDT), which is part of the neuronal circuitry responsible for REM sleep generation, ii) inhibits evoked excitatory glutamatergic responses in the same cholinergic neurons, and iii) significantly reduces REM sleep amount when microinjected into the LDT.

Alterations in sleep amount and architecture during infection can be seen as exquisitely tailored to support the generation of fever, which in turn imparts survival value. For instance, shivering is crucial for the generation of fever, but does not occur during REM sleep, because active thermoregulation is impaired during this sleep phase. This could explain why REM sleep is eliminated during development of fever. Moreover, IL-1 interactions with brain neurotransmitters affect other behaviors, beside sleep, and play a role in pain modulation.

MESOLIMBIC CIRCUITS FOR ANIMAL PAIN AND ANALGESIA

D. Fonda

Veterinary Clinical Sciences Department, Università degli Studi di Milano, via Celoria 10, 20133 Milano (Italy)

E-mail: diego.fonda@unimi.it

In humans and animals, main circuits for inhibition of pain have been found to act through the opioid disinhibition, although other mechanisms may be involved through serotonergic or adrenergic neurotransmission. During vertebrate evolution, the opioid receptors have been shown to arise firstly as □-receptors, afterwards as □□-□receptors, and more recently as □-□□receptors, and seem to be more type-selective in mammals than in non mammalian vertebrates. In animals, opioid receptors are nowadays demonstrated to be present in mammals, birds, reptiles, amphibians and teleost fishes [1]. Distribution of opioid receptors in human central nervous system has been recently clarified by positive emission tomography (PET): during acute pain, □-opioid receptor binding is increased in *amygdala* (AMY), *nucleus accumbens* (NACC), *thalamus* (THA) and rostral anterior cingulate gyrus cortex (ACC) [2], particularly reflecting the gate function for the pain threshold in THA, ACC and inferior frontal cortex (FC); the coding of pain intensity in periaqueductal substance grey (PAG) and posterior cingulate gyrus cortex (PCC); and the encoding of unpleasantness in posterior ACC [3]. Distribution of opioid receptors in animals has been recently better investigated. Using radioligand autoradiography, higher binding of □-opioid receptors in the FC, somatosensory (S1), and cerebellar (CeC) cortices and in midbrain (*colliculus*) were recorded in the horse than that in the dog, whereas there was higher binding of □-opioid receptors in the FC of dogs and in the CeC of horses [4]. In rats, using small animal PET combined with the glucose analogue [^{18}F]-fluorodeoxyglucose, electrical high frequency stimuli applied to the sciatic nerve was followed by induction of spinal long-term potentiation (LTP) and an acute metabolic response in S1, but by various slower metabolic adaptations in brain regions involved in nociception and descending inhibition, as well as AMY, PAG and dorsolateral pontine tegmentum (DLPT) [5]. In humans, using functional magnetic resonance imaging technique, neural substrates of classic circuits for acute pain have been recently identified in THA and S1, insular (IC) and prefrontal orbital gyrus (PFC) cortices [6]. In humans, two components of pain [7] have been recently diagnosed by imaging technique [8], the sensory-discriminative one situated in THA and S1, IC, and CeC, and the affective-emotional one situated in PFC, ACC, NACC, and sublenticular extended AMY). In animals, there is now evidence in most mammalian species for the confirmation of the former two pain components [9], to which could be added other two, hypothesized in man, the interoceptive autonomic one, demonstrated in primates [10], and the cognitive one, suggested by the placebo effect [11] and supposed to act also in animals [12].

Both endogenous and exogenous opioids are inhibitory neurotransmitters so that they can act only by disinhibition of other inhibitory neurotransmitters (e.g. GABA), producing analgesia. Analgesia may be considered as an inhibition of pain and acute pain as an alarm system. Since pain may need, differently from the other alarm system as temperature, touch, and proprioception, to be disactivated (analgesia) because of survival or other requirements, all vertebrates show to share with human beings opioid, serotonergic and noradrenergic receptors, to produce pain inhibition (analgesia) in occasion of survival, threats or other necessities, and to process emotionally pain. Because there are many pain pathways, so there are many types of analgesia (stimulation-induced analgesia, stress-induced analgesia, diffuse noxious inhibitory controls, counterirritation or surround analgesia, vagal nerve stimulation-induced analgesia, fear-induced analgesia, pain-induced analgesia), involving many other neurotransmitters than opioids and suggesting the recent approach to multimodal analgesia. Because there are more than one pain pathway and consequently many pain mechanisms,

it is now recommended, also for animals, than therapeutic protocols cope with the pain mechanisms, no longer with the pain symptoms [13].

1. In humans and animals, the main axis of this endogenous (non pharmacologic) and exogenous (pharmacologic) opioid inhibition seems to be the periaqueductal substance grey (PAG) and the rostroventromedial medulla (MRVM), at the mesopontomedullary level.

In the brain, pain is regulated by multiple overlapping neuroanatomic circuitries. The most frequently quoted for the opioid inhibition is the mesopontomedullary PAG-MRVM system. The PAG, named also central grey, is a circumventricular organ, tapestrying the aqueduct of Silvius (De la Boe), where it takes contact with the cerebrospinal fluid. The PAG [14] is constituted of four columns providing important connections: dorsomedial column projecting to AMY and HYP (part of mesolimbic circuit); dorsolateral column projecting to IC and ACC; lateral column connecting the spinomesencephalic tract with limbic system; ventrolateral column projecting to MRVM. The MRVM is constituted of *nucleus magnus raphe* (NMR), *nucleus paragigantocellularis*, lateral part (NrPGil) and *nucleus reticularis gigantocellularis* (NrGi) [15], which have shown to be involved in endogenous nociceptive descendent inhibitory pathways, but also to transmit facilitatory inputs, to control homeostatic physiological processes as micturition and sleep [16] or behavioral responses (the rostral "aggressive response" including howling, the caudal "flight response" and the ventrolateral "freezing " or tonic immobility response, including a sympatholitic, antipredator defensive behaviour) [17]. In the case of pain-induced analgesia, PAG projections from MRVM provide to transfer inhibitory serotonergic (dorsal, median raphe nuclei, NMR, *nucleus pallidus* and *obscurus raphe*), noradrenergic (NrPGil), opioidergic (NrGi) descendent inputs to dorsal horn of spinal cord (*lamina* II) in order to obtain antinociception. PAG opioid disinhibition of tonic MRVM inhibition supplied from GABAergic neurons have shown to activate these descendent inhibitory pathways, resulting in analgesia.

2. In animals, during acute pain, endogenous opioid release are supposed to be mainly dependent upon both the opioidergic mesolimbic loop, and the dopaminergic reward circuit.

There are in the brain many circuits providing for release of opioids. In animals, two systems seem to be nowadays most important than others. The opioidergic mesolimbic loop, named also the " morphine system" is constituted of opioid cells scattered in PAG, AMY, NACC, [18] and now supposed to be correlated with striatal enkephalin system [19] and extended to HYP [20]. The dopaminergic reward circuit, named also mesostriatal [21] or mesolimbic system [22], is constituted of dopaminergic cells scattered in ventral tegmental area (VTA), NACC, and PFC, that can be activated by opioid release [23] or can produce opioid release in the presence of conflicting motivations, such as hunger or a threatening predator [21]. Recently other structures including AMY, hippocampus (IPP), lateral habenular nucleus, *substantia nigra*, pedunculopontine nucleus and the raphe nuclei have been considered to be key components of the reward circuit [24]. Using functional magnetic resonance imaging technique, morphine infusion resulted in increased signal changes in reward structures including NACC, sublenticular extended AMY, IPP and orbitofrontal cortex, a decreased signal in cortical areas (sedative effect), PAG and ACC (analgesic effect) and an increased signal in HYP [25]. Using PET, both opioid and placebo show to involve associated brain areas, particularly rACC, suggesting the participation of higher order cognitive networks [26].

Clinically, there is now evidence for a contribution of attention and expectation on descending modulatory pathways. Attentional modulation of pain may be obtained by visual, auditive or other distraction, involving PAG-MRVM system: pain intensity and reactions were predictabily lowered by distraction. Pain expectancy or anticipation seem to be the most important pain-predictive contextual cues. Pain expectation or prediction may have negative (fear) or positive (reward) effect, presenting a large degree of variability between the certain and uncertain pattern. Therefore, reward may be considered the result of a certain positive expectation, whereas being afraid of pain is recognized to increase pain intensity, in the absence of a noxious stimulus also. Through recent functional magnetic resonance neuroimaging studies, neural substrates of certain and uncertain expectation have shown to be the rostral ACC and posterior *cerebellum*, and respectively PFC, ACC

and IPP [27]. Ventral striatum and particularly NACC has been studied to be involved in a particular form of reward, considered to be the addiction, Molecular mechanisms of addiction, through valid animal models (mouse, rat), show to involve dopaminergic [28] and opioid release in the reward-stress circuitry (central nucleus of AMY, bed nucleus of stria terminalis, and NACC) [29]. Support for endogenous opioid-mediated pain-modulating pathways may be obtained through both mesolimbic and reward circuits [21] and may be demonstrated by neural substrates of the placebo-analgesia (activation of NACC, dopamine release in NACC, triggered activation of the endogenous opioid system, ventral loop of the basal ganglia circuitry) [30]. Interestingly, these brain areas have shown to be important for the animal low-order consciousness. In the past, seven basic emotional feelings (seeking, rage, fear, lust, care, panic, play) were assessed in animals [31] and recently six subcortical midline sunstrates (PAG, superior colliculi, adjacent mesencephalic locomotor region, preoptic areas, HYP, dorsomedial thalamus) [32] were proposed as site for animal awareness, considered to be the so called "core self" [33].

3. In vertebrate evolution, evidence for these endogenous opioid circuits makes the basis for the homologous circuits supposed to act in human beings for modulating acute pain and allowing the human and animal non-pharmacological analgesia.

Different cortical and subcortical regions process different component of multidimensional nature of pain. Neural substrates of pain pathways in animals have shown to be similar [10] to those in humans [34]. Neural substrates implicated in conditioned analgesia in animals are the brainstem to spinal cord circuits, which are highly conserved in a variety of mammals species, including marsupials, rodents, carnivores, and primates [35]. Importantly, the distribution of neurotransmitters in this circuitry is also conserved across species, including rats and humans [36]. Although more careful investigations would be necessary to be performed in single and domestic species, some important differences have arisen in cats about the spino-reticular and spino-mesencephalic pathways [37], the five separate spino-PAG [38] and the larger spino-parabrachial circuits [39]. In conclusion, this endogenous opioid-mediated pain modulatory system has been recognized to exist firstly in mammalian species and more recently in human beings, so that there is a body of evidence supporting the notion that pain-modulating circuitry, homologous to PAG-MRVM opioid system demonstrated in animals, are present in humans [35].

Clinically, it is important understanding that endogenous opioid release may be an important therapeutic opportunity for animals as well as for paedriatric patients. In the last two decades, the use and diffusion of many methods or interventions to obtain nonpharmacological analgesia have remarkably grown in paediatric [40] and animal patients. Together with many techniques of complementary and alternative medicine, nonpharmacological interventions are based not only on the opioid mechanism of the mesolimbic loop, able to induce "tender love care", but on the management of all environmental effects of pain on the animal five senses: comfortable body temperature (warm-cold) and moisture (dry-wet), touch contact surface (smooth-rough), minimal light (vision) or noise (hearing) in environment, friend smell or pheromones (olfaction). Other nonpharmacological pain management methods are based on parental effects like maternal touch, kangaroo care, swaddling, facilitated tucking, non-nutritive or nutritive (glucose) suckling, rocking, or physical effects on pain like cryotherapy, hydrotherapy, massage therapy, chiropractic and osteopathic manipulations. It is worth noting that also play, laughing, tickling, pins [41], and social contacts [42] may contribute to relief of acute pain, not only in rats. Other non-pharmacological therapeutic techniques, applied also in animals, have shown to involve for relief of pain mechanisms in part opioid, like acupuncture (OPP), in part anti-inflammatory, like laser-therapy, pulse magnetic fields therapy, transcutaneous electrical nerve stimulation, ultrasound therapy, extracorporeal shock wave therapy.

4. During chronic pain, particularly the neuropathic one, conditions and effects of these circuits seem to change, but in humans and animals are still to be evaluated.

To understand acute and chronic pain mechanisms, the proposal of the multidimensional theory of the body self neuromatrix [42] has shown to be essential. From four concepts derived from the

analysis of phantom limb phenomena (pain may occur in the absence of any inputs from the body - stimuli may trigger pain patterns but do not produce them – the body is perceived as the "self" - the body-self is "built-in" by genetic specification and modification by experience), Melzack has derived a new conceptual nervous system as the theory of a body self neuromatrix, involving four components or steps: sensory inputs sculpt their line in the neuromatrix (thalamocorticothalamic and limbocorticolimbic circuits); repeated cyclical processing and synthesis of these nerve impulses create in this neuromatrix a neurosignature; this neurosignature projects both in brain regions (sentient neural hub), where it is converted and transduced in the stream of awareness, and in spinal cord neurons to activate pattern of movements (actions) to bring about the desired goal. Thereby, pain experience may be considered not as a purely sensory phenomenon, but a multidimensional experience, including sensory-discriminative, affective-emotional, cognitive and interoceptive components. Moreover, such an interpretation may be considered to be partially shared also with other animals [44], non-human primates and vertebrates, provided that it is proportionate to functions and connections supplied by neural substrates.

Clinically, processing of chronic pain is different from that involving the acute one. Acute pain processing involves more than one neural substrate, possibly in the following order: at the mesopontomedullary level, producing involuntary neurophysiological responses; in the parietal cortex, coding pain site, intensity, type; in the limbic system, decoding pain emotion and memory; in the prefrontal cortex, planning behaviour; in the parietal cortex, producing voluntary cognitive response; in the basal ganglia, producing voluntary locomotory response; in the PAG, allowing pain facilitation or inhibition (analgesia). On the contrary, processing of chronic pain, without more interest in coding the sensory component (localization, intensity) of this repeated pain, continues to elaborate pain emotion and memory between cortex and limbic substrates, participating with conditioned involuntary neurophysiological responses and without being able to produce voluntary responses. [45].

Our understanding of acute and chronic pain mechanisms requests a growing attention not only to involved neural substrates, but also to the contribution of cellular remodelling and biochemical changes, regarding particularly the immune mechanisms in the inhibition of pain (analgesia). A recent challenge to conventional concepts regarding not only the acute pain, but particularly the chronic neuropathic one, is the contribution of immune cells and glia to the development and the persistence of pain after nerve injury. Neurons resulted nowadays to be no more the only responsible for the pathophysiological changes that drive maladaptive, neuropathic pain. This shifting in our understanding suggest to consider hyperalgesia and allodinia no longer maladaptive, but adaptive because - for example- the participation of peripheral immune cells in wallerian degeneration could be considered as a facilitation for healing and regeneration of injured axons so to provide novel opportunities for pain therapeutic approach [46].

PROGRESS IN ACUTE PAIN ASSESSMENT

When debating the nature of pain in animals, considerable parallels can be drawn with the situation in human infants (Flecknell & Waterman-Pearson 2000). In adult humans, the ability to provide direct verbal communication, complete pain questionnaires or scoring systems, or to directly manage analgesic dosage using patient controlled analgesia systems allows reasonably reliable estimates to be made of the degree of pain and the efficacy of pain control. In young human infants, written and verbal communication is not possible; nevertheless, extrapolation from adult humans, coupled with objective demonstrations of the adverse effects of surgical stress, has led to a huge increase in research focused to this area (McGrath & Unruh 1989). In human infants, the most widely used techniques have been pain scoring systems based upon criteria such as crying, facial expression, posture and behavior.

Biochemical and endocrine parameters, such as blood cortisone concentrations or catecholamine concentrations, have been proposed as indicating pain. A major problem in interpreting the significance of these changes is the influence of surgery and anesthesia, which markedly alter many of these variables, even in patients which are pain free. Therefore endocrine parameters are not clinically helpful when assessing immediate postoperative pain. Similarly, increases in heart rate or blood pressure that can be associated with pain, are relatively unspecific parameters as they can also be related to hemodynamic changes as a result of surgery (Flecknell & Waterman-Pearson 2000).

The basic methodology selecting clinical signs which might be due to pain has been used to provide pain-scoring systems during the perioperative period in veterinary clinical patients (Flecknell & Waterman-Pearson 2000). Attempts at scoring have either used descriptive ratings converted to numerical scores to allow for comparisons, or have used visual analogue scoring systems (VAS) (Nolan & Reid 1993; Pascoe & Dyson 1993). Particular problems noted were considerable between observer variation and the poor predictive value of certain of the parameters scored. It appears that if the number of observers is restricted, and the criteria used was carefully selected, reasonable agreement can be achieved. Even though some pain scoring systems have been efficiently used for chronic pain evaluation, there applicability for postoperative acute pain is limited (Morton & Griffiths 1985). A problem with many of these 0approaches is the difficulty associated with scoring of animal behavior, motor function and food intake during the recovery phase from anesthesia.

However, scoring systems for postoperative pain assessment have been validated (Firth & Haldane 1999). More recently, a short composite pain scale has been effectively used for acute pain assessment in dogs (Murrell et al., 2008). Although not validated, a couple of clinical studies have used postoperative pain scales that can be used as a guide to assess postoperative pain in dogs and cats (Rohrer Bley et al., 2004; Wenger et al., 2005).

PRACTICAL APPROACH TO POSTOPERATIVE PAIN ASSESSMENT

Pain management should be species-specific and patient-oriented, as important variations occur among species. Not every animal will perceive pain in the same way and not always similar procedures will cause similar painful sensations. It is important to document the results of pain assessment and the efficacy of the treatment, as further adjustments on the overall analgesic management strategy should be based on the individual findings. Most patients recovering from anesthesia after surgery will experience some degree of pain. However, other patients may be pain relieved after some procedures (i.e. repositioning of coxofemoral luxation). Some species (i.e. rabbits, sheep) will not display easily recognizable signs of pain or discomfort and might suffer

quietly. Others will show dysphoria due to anesthetic or analgesic administration that might confound pain evaluation. A good way to start is to know the normal behavior for the evaluated species and/or to observe the patient before the surgical procedure. Monitor if the current illness process is causing signs of pain and check the behavioral reactions to human interaction and to foreign places. During anesthesia pre-medication check for the potential behavioral reactions to opioids or benzodiazepines as they may cause dysphoria that might be confounded with signs of pain during the postoperative period, particularly in some species (i.e. dogs, cats, horses).

Throughout the recovery phase from anesthesia it is important to evaluate the patient respiratory rate and pattern and assess for anxiety. Bear in mind drugs that had been administered to distinguish vocalization as a result of pain or side effects to these analgesics (i.e. opioids, benzodiazepines, ketamine). Slowly approach the patient and evaluate its reaction to human interaction and palpate gently the surgical area and also non operated areas and compare the patient reactions to both manipulations. For species that may not display signs of pain or discomfort when approached, it is helpful to evaluate their gait or, whenever possible, the behavior in their natural environment, from a distance. If the patient shows abnormal behaviors (i.e. loss of appetite, decreased interaction with environment) or is somewhat anxious and vocalizes and turns the head when palpating the surgical area only, a test dose of an analgesic may be administered (i.e. buprenorphine, methadone, morphine). If administration of an analgesic diminishes the changes associated with abnormal behaviors or manipulation of the operated area, this supports the hypothesis that the changes were, at least in part, pain related. Clearly it is important to establish that the analgesic did not have non-specific effects in normal animals that would influence the variable studied (i.e. extreme sedation might be confounded with pain relief). Alternatively, if vocalization and/or agitation are observed and a reaction to opioids or benzodiazepines is suspected, the administration of a specific reversal might be appropriated (i.e. naloxone or butorphanol, flumazenil). Keep in mind that antagonization of opioids might reverse their analgesic effects and other non-opioid analgesic drugs should be considered in such situation (i.e. □2-agonists, non-steroidal anti-inflammatory drugs).

Anxiety might be the result of several factors such as pain, separation or unknown environment. If pain has been exclude as the cause for anxiety, sedatives (acepromazine or dexmedetomidine) or simple human interaction and tender loving care (TLC) will help in reducing the stress. It is important to realize that many patients might be uncomfortable after anesthesia as a result of a full bladder that needs to be evacuated. In addition, re-evaluate bandage tightness and position of the body in the postoperative period as these factors might be also the source for stress or pain. A calm room and/or comfortable bedding or for some species, an enriched environment will also alleviate patient discomfort.

ANALGESIC DRUG SELECTION

The use and choice of analgesic agents are based on the species-related pharmacological profile of these drugs and a thorough patient assessment that includes a physical exam; an evaluation of the patient's history, underlying or preexisting conditions, and presenting complaint; and a laboratory evaluation of an appropriate database (Hellyer et al., 2007). A multimodal approach to pain management allows for using lower doses of a combination of analgesic and takes advantage of their different modes and sites of action. Commonly used analgesic protocols will include an opioid before an elective surgery, in combination with tranquilizers or sedatives (i.e. phenothiazines, □2-agonists) to enhance sedation and analgesia. The use a local anesthetic to block the transmission of noxious stimuli before incision or to potentiate analgesia postoperatively, has being gaining more adepts lately as local anesthetics have been associated with less postoperative chronic pain incidence. Epidural catheters or wound infiltration catheters can be placed during anesthesia to prolong the benefits of local blockade throughout the postoperative period. Prior anesthesia or during anesthetic recovery, the use non-steroideal anti-inflammatory drugs help to decrease the actions of inflammatory mediators released during surgery. However, the species-specific pharmacokinetic profile and the potential side effects of these agents should be taken into consideration. Opioids are still the most widely used agents to control postoperative pain as they

have minimal cardiovascular side effects. Lidocaine or ketamine infusions can be used in the postoperative period to alleviate severe pain in combination with opioid infusions when local blockade is not possible. Lately, tramadol has been incorporated to treat mild to moderate pain in the postoperative period, generally associated with non-steroideal anti-inflammatory drugs. If sedation is required together with analgesia, infusions of □2-agonists (i.e. medetomidine or dexmedetomidine) might be a valid option.

The International Association for the Study of Pain (IASP) defines that *the inability to communicate does not negate the possibility that an individual is experiencing pain and is in need of appropriate pain-relieving treatment*. Pain is a combination of both peripheral inputs and neurophysiological processes within the central nervous system. In mammals, opioids are often chosen for moderate pain relief,[1] while the use of opioids in avian medicine is limited and not broadly extended.[2]
The opioid drugs act on specific opioid receptors. Butorphanol is mainly acting as agonist on kappa receptors, while the mu receptors are usually triggered by opioids such as morphine.[3-4] The relative proportion of mu and kappa receptors in the forebrain of pigeons correspond to 14% and 76%, respectively[5] whilst in chickens (23% and 20%, respectively)[6] is remarkably close to those in mammals (29% and 37%, respectively).[5]Therefore, depending on the similarity of other avian species to pigeons or chickens, kappa or mu agonist opioids like butorphanol and morphine are both options to provide analgesia in birds.
Quantification of the analgesic effect of drugs in birds is challenging and no validated scores are available. The tools used in the avian species are based on the assessment of the evoked nocifensive answer in response to mechanical, thermal or electrical stimulation. Quantification of changes of the minimum anaesthetic concentration (MAC) can provide information that allows comparison between different analgesic drugs when interacting with volatile agents. MAC is defined as the concentration of an inhalatory anaesthetic that prevents purposeful movement following a supra maximal painful stimulus in 50% of the individuals tested.[7] An effective analgesic dose would lead to a reduction of the MAC.
Butorphanol has been reported to potentially have an analgesic effect based on reduction of the requirements of inhalant anaesthetics, in cockatoos (*Cacatua spp*.) (1 mg/kg),[8] African grey parrots (*Psittacus erithacus*) (1 mg/kg)[9] and Hispaniolan Amazon parrots (*Amazona ventralis*) (2 mg/kg)[10] after intramuscular administration. In chicken, the effect of various drugs on MAC has been determined.[11] Butorphanol at a dose of 1 mg /kg IM, did not produce MAC reduction. Morphine has been described to have an isoflurane-sparing effect in chickens after progressive intravenous administration.[12]
However, a decrease on MAC due to the effect of an analgesic drug could lead to an inadequate depth of anaesthesia. Objective assessment of depth of anaesthesia is performed in human medicine by use of Bispectral Index (BIS).[13-14] In birds, first data [11] showed that BIS is a useful tool for this purpose as well.
MAC reduction caused by opioids is not only an objective measure that quantifies the analgesic potency of a drug, but also a goal in balance anaesthesia: if less inhalation anesthetic can be used, cardiovascular function will be improved. This would contribute to decrease the high mortality rate related to avian anaesthesia (5.5%) in comparison to 0.17% in dogs or 0.02 – 0.005% in human medicine.[15]

The purpose of this study was to evaluate the dose-dependent changes on the MAC of isoflurane produced by butorphanol and morphine in chickens.
Eight adult healthy chickens underwent individual MAC determination of isoflurane with the up and down method using toe-pinch stimulation. Allowing 1-week washout period between treatments, the individual MAC was determined after intramuscular administration of saline (0.5, 0.75 or 1 ml/kg), butorphanol (2, 3 or 4 mg/kg) or morphine (5, 7.5 or 10 mg/kg). All the chickens received during the three first anesthesias, randomly and by a blinded observer, the lowest dosage of every drug. Thereafter, they received the medium and the high dosage. Results are reported as median and were analyzed using Friedman and Tukey tests when corresponded. Significance was set at $P < 0.05$.
The only remarkable effect measured on MAC was a 22 % reduction of isoflurane with 10 mg/kg morphine. The MAC values for the low, medium and high dose of saline were 0.63 %, 0.60 % and 0.71 %; butorphanol 0.70 %, 0.60 % and 0.65 % and morphine 0.70 %, 0.53 % and 0.45 %, respectively. The individual MAC of isoflurane obtained for our group of chickens was lower than in previous studies in chickens (1.25%[12] and 1.15%[16]) and other avian species i.e. cockatoos (*Cacatua spp.*) 1.44%[8], sandhill cranes (*Grus canadensis*) 1.34%[17], peking ducks (*Anas domesticus*) 1.30%[18], or thick-billed parrots (*Rhynchopsitta pachyrhyncha*) 1.07%.[19]
No significant differences were observed between groups for heart rate (260 to 300 bpm) or non invasive blood pressure (85 – 100 mmHg). Bispectral index monitored the electrical activity of the brain revealing a correlation to the anaesthesia event; BIS for saline, butorphanol and morphine for the low dose were 68 (45 – 80), 54 (38 – 71) and 69 (55 – 79); for the medium dose 77 (35 – 85), 72 (39 – 84) and 72 (61 – 81) and for the high dose 39 (34 – 67), 38 (34 – 46) and 36 (34 – 41), respectively.
The dosage order was not randomized and therefore, chickens receiving the high dose of saline had been at least 6 times under anesthesia. Further studies are needed to investigate whether repetitive anesthesias depress the electrical activity of the brain in chickens.
We conclude that significant changes on MAC were only observed with 10 mg/kg morphine, which produced an isoflurane-sparing effect of 22 % in the chickens of this study. These results have to be carefully interpreted as the method is based on the reaction of the animal to supra-maximal stimulation and thus it can be easily biased.
This study was supported by the Stiefel-Zangger Foundation and the *Nachwuchsförderungskredit* of the University of Zurich.

ANALGESIC MANAGEMENT OF CHRONIC OSTEOARTHRITIC PAIN

A Bufalari, C Maggio

Corresponding author email: antonello.bufalari@unipg.it

Osteoarthritis (OA) is a progressive degenerative disease of synovial joints, characterized by maladaptive pain during rest and joint use, lameness, destruction of articular cartilage and bony remodelling.(1) OA is generally secondary to congenital and developmental abnormalities (elbow incongruety and dysplasia, osteochondritis dissecans, hip dysplasia); joint trauma such as fractures or ligamentous injuries; inflammation such as infections or immune-mediated diseases; neuropathic, neoplastic or iatrogenic causes.(1) OA affects all the component of the joint including cartilage, subchondral bone, synovial membrane, synovial fluid, ligaments and tendons as well as periarticular soft tissue. Once the disease process begins, a progressive cascade of mechanical and biochemical events occurs which determines maladaptive pain associated with an altered pain processing system (peripheral sensitization and central pain pathways). OA pain is caused by aberrant functioning of a pathologically altered nervous system, with key mechanistic drivers from peripheral nerves and central pain pathways. Pain perception does not simply involve an analysis of afferent noxious input relayed by a hard-wired system. Also, the neural transmission system is plastic and it is altered by previous experiences, leading to spontaneous pain, allodynia, hyperalgesia.(2) In the same way the peripheral terminal of the nociceptor can be sensitized, resulting in amplification and facilitation of synaptic transfer and NMDA mediated cellular wind-up which leads to central sensitization or hyperexcitability.(3) The following modifications can occur in this situation: synaptic-mediated activation of intracellular signal transduction pathways leading changes in gene expression; changes in function and anatomy of spinal cord; humoral factors potentiating central sensitization; peripherally produced factors act on central endothelial cells to produce IL-1b, which increases COX-2 expression and facilitates production of PG_s which facilitate synaptic transmission and excitability; upregulation of COX-(2) and prostanoids centrally drives development of central sensitization; increased sympathetic activity. When treating OA, the goals are to control joint pain, regain normal joint function, prevent cartilage destruction and fibrosis to preserve joint range of motion.(1) Analgesic treatment of OA pain includes administration of anti-inflammatory, opioids (including transdermal administration) and other analgesic drugs. In most cases, these drugs must be used in combination with weight reduction, proper nutrition, exercise control, physical therapy, and OA disease-modifying agents. Treatment for OA pain is effectively limited to the available products. The number of them proved to provide safe and effective treatment does not change rapidly. The approved pharmaceutic analgesic agent are the most reviewed products. The decision of when and how to treat OA is often based on a combination factors such as efficacy, product availability, cost, personal experiences, easy to administration and success or failure of previous treatments.(4)

NEUROPATHIC PAIN IN ANIMALS. PHYSIOPATHOLOGIC CONSIDERATIONS AND THERAPEUTIC APPROACH

Giorgia della Rocca, Alessandra Di Salvo, Maria Teresa Mandara - Centro di Studio sul Dolore Animale (CeSDA), Facoltà di Medicina Veterinaria, Perugia, http://centri.unipg.it/cesda

Key words: neuropatic pain, animals, causes, treatment

SUMMARY

Neuropathic pain originates from a primary dysfunction of the peripheral or central nervous system (NS). As in human beings, in animals a number of conditions during surgery or in traumatic, inflammatory, and metabolic disorders, can lead to the development of neuropathic pain. Since animals are unable to verbalize, neuropathic pain is more difficult to be diagnosed than in humans. Once neuropathic pain has been diagnosed, an appropriate therapy should be prescribed, considering not only the well known analgesic drugs such as FANS and opioids, but also molecules such as gabapentin, amantadine, imipramine and others, as well as adjuvant techniques, addressed to the owners with accurate instructions on observation and reporting pain behaviour.

INTRODUCTION

Pain can be classified into physiological (adaptive) and pathological (maladaptive) pain.

Pathological pain is no longer associated with tissue damage or a repairing process, but it results from a damage (neuropathic pain) or abnormal function (functional pain) of the NS. This pain has no longer a space-time correlation with the damage that caused it, since it is the expression of an abnormal sensory process, and it is usually persistent (over the stimulus that caused it) or recurrent. It is due to plastic often irreversible changes, occurring in the central nervous system, which get the system activated even in absence of nociception (dis-nociceptive or not nociceptive pain). This pain is characterized by loss of temporariness and auto-limitation, features of adaptive pain (1, 3, 4).

Neuropathic pain is defined as “pain initiated or caused by a primary lesion or dysfunction of the nervous system”. This definition, however, is quite unclear because the term dysfunction is not specific. Another proposed definition is “pain that develops as a direct result of a lesion or a disease affecting somatosensory system”. Therefore, this pain results from an abnormal activation of neural pathways of pain perception due to a damage or a dysfunction affecting peripheral nerves and dorsal roots (peripheral neuropathic pain), spinal cord or brain (central neuropathic pain) (1).

With respect to inflammatory pain, neuropathic pain occurs in the absence of nociceptor stimulation, following an ectopic activation of peripheral or central neurons (dis-nociceptive pain).

A persistent increased excitability of nociceptors (which are sensitized from an injury and do not return to normal level of excitability after the resolution of the tissue damage), reactivation of the action potential along the fiber (in case of dismyielination or demyelination), formation of neuromas (characterized by neo-nociceptors synthesis, formation of ephapses and central sprouting of Aβ fibers terminals), degeneration of central terminals, dis-inhibition, neuronal hypersensitivity and central sprouting of unharmed central terminals are some of the molecular mechanisms underling peripheral neuropathic pain.

Molecular mechanisms of central neuropathic pain are probably attributed to an imbalance of glutamatergic and GABAergic transmission in the CNS, especially in the thalamic-cortical axis, and to the consequent hyperactivity of thalamic and cortical neurons, which follows injury to any neuraxis level (3).

Today it is assumed that animals show the same neurophysiological pathways and pathogenic mechanisms than of human pain. Moreover, after a consistent injury they also show plastic changes of NS producing a transition from adaptive to maladaptive pain. Based on these premises it seems reasonable that also animals can suffer from neuropathic pain.

CONDITIONS ASSOCIATED WITH NEUROPATHIC PAIN IN ANIMALS

Based on both direct clinical experiences and similarities with human medicine, it is possible to define a number of conditions that may be associated with neuropathic pain in animals.

Neuropathic pain in animals can be due to:

1. accidental or surgical trauma;
2. primary lesions of the peripheral or central NS;
3. visceral disorders.

1. A tissue damage, such as those caused by trauma or invasive surgery, if not properly and promptly treated, can produce plastic changes in the NS circuits which facilitate the maintenance of pain even when the afferent stimulation ceases. Moreover, in many surgical procedures, nervous tissue may be entrapped by accident in a suture or in fibrous tissue activating neuropathic pain, as studied in animal models. Among the conditions potentially responsible of neuropathic pain, we can mention: perineal and inguinal hernia reduction (pudendal nerve entrapment), sacral and pelvic fractures or their reduction (damage to the femoral nerve and cauda equina and/or pudendal nerve entrapment), surgical procedures on limbs (entrapment of limb nerves), amputation (formation of neuromas), lumbo-sacral lesions (eg degenerative lumbosacral stenosis or cauda equina syndrome, idiopathic stenosis, discospondylitis , trauma, cancer, inflammation, impaired vascular functions and congenital abnormalities) and spinal cord injury (eg trauma, ischemia, hemorrhage, intervertebral disc herniation, fibrocartilaginous embolic myelopathy, vertebral osteomyelitis and discospondylitis).

2. Among the causes responsible for neuropathic pain from primary lesions of the peripheral nervous system we can indicate tumors, diabetic neuropathy, polyradiculoneuritis and functional disorder of vascular innervation.

Central nervous system tumors, congenital and development lesions (eg syringohydromyelia), vasculitis and meninges inflammation (eg granulomatous meningoencephalomyelitis, aseptic meningitis), represent some of the primary lesions causing central neuropathic pain.

3. Among the causes of visceral neuropathic pain, feline interstitial cystitis, Idiopatic Bowel Disease (IBD), pancreatitis and pancreatic cancer are some the most implicated (2).

DIAGNOSIS OF NEUROPATHIC PAIN

Diagnosis of neuropathic pain is crucial, because the mechanisms involved in the genesis of this type of pain will condition the therapeutic approach.

Clinically, neuropathic pain may be attributed to positive or negative signs, and autonomic dysfunctions. Spontaneous and evoked pain, such as allodynia, hyperalgesia, loss of sensitivity and vascular and sweat glands dysfunction are the most frequent clinical signs.

In both human and veterinary clinical practice, diagnosis of neuropathic pain is not to easy.

In human medicine, specific diagnostic tests as well as verbal indicators and scales for the assessment of neuropathic pain play a key role in the diagnostic process. Generally, in the absence of an actual tissue damage the diagnosis of human neuropathic pain is mainly based on anamnesis data consistent with nerve damage and on specific clinical signs, such as allodynia, secondary hyperalgesia, dysesthesia, and autonomic features.

Of course, given the inability of animals to verbalize, in veterinary medicine diagnosis of neuropathic pain is even more complex than in humans,. The approach used in human medicine, namely clinical monitoring, with particular emphasis on history and physical examination of the sensitivity, can also be applied to veterinary medicine. The presence of neuropathic pain can be suspected when a “personality” change of animals occurs, as a consequence of sensory perception and emotional pain. Behavioural changes, such as numbness or aggressivity, may be noticed by the owners along with clear signs of pain. During the diagnostic process, to interact with animals is very useful: movement and palpation of the painful area may evoke a tenderness not proportional to that expected, suggesting the presence of neuropathic pain. Algometric, thermal tests, and electrodiagnostic methods are being object of study also in veterinary medicine, and it is likely that

with time scales for the assessment of neuropathic pain will be arranged also in veterinary patients (1, 2).

TREATMENT OF NEUROPATHIC PAIN

Several studies showed reduced response to opioids in patients suffering from neuropathic pain. Clinical evidence also showed that some opioids, especially pure μ-agonists, can promote spinal excitation when used at high doses, paradoxically implementing the pain level. From the foregoing, it is clear that opioids do not have a great therapeutic response in neuropathic pain treatement, but in severe or breakthrough pain, such as that occurring in some cancers, they must nevertheless be considered within the adopting multimodal analgesic protocols.

In veterinary literature there are not sufficient data on efficacy and pharmacokinetic features of tramadol in neuropathic pain useful to provide appropriate dosage in dogs or cats; however, in some situations its use is still recommended, with doses coming from human medicine or relied on clinical experience carried out on animal patients.

In animal models of neuropathic pain, allodynia and hyperalgesia are often responsive to NMDA receptor antagonists, such as ketamine, amantadine and dextrometorfane. Ketamine is a dissociative anesthetic commonly used in veterinary medicine, that has recently been tried in sub-anaesthetic doses to contrast neuropathic pain. Amantadine has recently been introduced in the management of animal chronic pain. Dextrometorfane is an oral antagonist of the NMDA receptor, recommended in the management of human neuropathic pain. Unfortunately, it is not absorbed when administered orally to dogs, and this is why it is not recommended in this species.

The up-regulation of voltage-dependent sodium ion channels (that may occur in damaged sections of nerve fibers) accounts for the excellent analgesic activity of local anaesthetics in neuropathic pain. Lidocaine, tocainide, mexiletine and flecainide seem to relieve neuropathic pain in some human patients, but at present there are no evidences in veterinary medicine about their analgesic effects in dogs and cats with neuropathic pain.

Alpha$_2$-adrenergic agonists administered by spinal route have been shown to counteract dysesthesia and allodynia observed following a peripheral nerve injury in rats and humans. Medetomidine, and more recently dexmedetomidine, are the α_2-agonists most commonly used in veterinary medicine.

The central action of NSAIDs makes these drugs able to contrast the *wind-up*. However, so far there are no studies on their efficacy in the management of neuropathic pain in animals. From a clinical point of view, it has been noticed that, under pain of presumably neuropathic origin, adding a NSAID to an opioid improves analgesia and pain scores, if compared to the use only of the opioid.

Gabapentin, pregabalin and lamotrigine belong to the class of anticonvulsants. Recently, these drugs have been recommended for the treatment of neuropathic pain in human patients, and they are taking place even in veterinary practice.

Because of their ability to modulate the action of serotonin and norepinephrine at central and peripheral level thus reinforcing the inhibitory descending system, drugs such as tricyclic antidepressants (eg imipramine and amitriptilina) and serotonin and norepinephrine re-uptake inhibitors (eg, fluoxetine and duloxetine) have recently found application as adjuvants in the treatment of neuropathic pain.

Even non-pharmacological treatments, such as acupuncture and physical rehabilitation, begin to be considered for the management of neuropathic pain (2).

CONCLUSIONS

It is now clear that neuropathic pain, frequently associated with chronic pain, may also occur as a consequence of an acute situation involving nervous tissue.

An early recognition of an animal “at risk” of developing chronic neuropathic pain from an acute condition is essential to establish an appropriate pharmacological approach before, during and after surgery, with the aim to prevent the sensitization process and the stabilization of a situation that is

difficult to diagnose and treat later on. The use of preemptive analgesia is essential in view of reducing afferent stimulation and a subsequent development of sensitization.
In addition, whenever an animal should be subjected to surgery, it may be careful to identify the nervous tissue, always to handle it with great care and ensure that it has not been entrapped into a surgical legation, thus preventing the potential development of neuropathic pain.
An accurate diagnostic process is also crucial for the identification of neuropathic pain without apparent injury.
To manage neuropathic pain, drug therapies are in use applying different classes of molecules, every of which acts at a specific level of the pain pathway (multimodal analgesic therapy). "Unconventional treatments", such as acupuncture and physical therapies, are also applicable.
After a diagnosis of neuropathic pain, the best approach we can adopte is to use a multimodal drug regimen in order to try to alleviate or eliminate suffering in our animals, thus improving their life quality and respecting one of the *five freedoms* related to animal welfare.

PAIN ASSESSMENT OF INTERNAL MEDICAL DISEASES IN DOGS: PRELIMINARY OBSERVATIONS

M.B. Conti, G. della Rocca, M. Duranti

Dipartimento di Patologia, Diagnostica e Clinica Veterinaria, Facoltà di Medicina Veterinaria, Università degli Studi di Perugia, via S. Costanzo 4, 06126 PERUGIA

mariabeatrice.conti@unipg.it

Introduction - Pain is a sensory and emotional experience which is not always clearly identified, especially in non verbilizing patients. In order to reduce the effects of variability between operators, pain scales have been developed in humans and some of them have been adapted to dogs undergoing surgery [1, 2]. However, little has been done to assess pain associated to internal medical diseases (IMD). The purpose of this work is to provide the results of a preliminary study, carried out in a group of dogs referred to the Teaching Veterinary Hospital of the Faculty of Perugia, aimed to recognize pain in subjects affected by IMD.

Methods –61 dogs that differed in age, sex, and breed were divided into 4 groups: Group A: gastro-enteric diseases (n° 18); Group B: respiratory diseases (n° 20); Group C: urinary tract diseases (n° 13); Group D (control group): clinically healthy dogs (n° 10). Furthermore, each animal was evaluated by 3 groups of operators whom have different levels of training (students, recent graduates, and teachers). The subjects were observed for a time ranging from 20 to 30 minutes: starting with the patients simply being placed in the hospital's cages, then in the treatment room, free to walk around and ultimately outdoors walking on a leash. The observers, whom were familiar with the patient's history, reviewed a questionnaire filled out by the owner (schedule 2), which contained information on the usual behaviour of the animal, and then performed a clinical examination. Hospitalized dogs were assessed 4-5 times per day. Observations were then recorded in a pain score sheet developed by extrapolating pain indicators from existing animal pain scales and contributing new ones. Obtained results were compared with those achieved by Simple Descriptive Scale (SDS), Numerical Rating Scale (NRS) and the Glasgow Composite Pain Tool.

Results and discussion – By using SDS, 47 of the 51 dogs affected by the different group diseases showed signs of pain (32/47 of mild intensity, 12/47 moderate, and 3/47 severe); 4 subjects showed no pain. Moreover, considering the differences amongst the type of diseases, almost all dogs from Group B (respiratory diseases: 15/20) and Group C (urinary tract diseases: 9/13) had mild pain; whereas animals from Group A (gastro-enteric diseases) presented a 50% mild and moderate pain. By using NRS, scores of 3 and 4 were assigned to more than half (n° 27) of the subjects; in 6 cases the score was 5, and a score of 1 was attributed to the remaining animals, except for 2 dogs which were given the score of 0. Considering each group as separate, the scores included values between 3 and 7 in Group A, between 1 and 5 (with a prevalence of 3 and 4) for Group B, and between 3 and 4 (with a prevalence of 4) in Group C. Ultimately, The Glasgow Composite Pain Tool proved to be inappropriate as expected in the assessment of pain caused by IMD. Behavioural observations easily allowed a differentiation between reactions due to fear and pain, furthermore keeping a record of the animal's behaviour in different situations. The initial impression of the different observers inherent to the presumed level of pain after the assessment of the dogs in the cages, was generally modified once the kennel door was opened and the animal let free to explore his/her surroundings. As a matter of fact, almost all dogs that appeared to be depressed or aggressive, became more active and sociable out of the cage. Only 2 cases (2 out of 4 affected by infectious gastroenteritis), which were severely depressed, and in subjects suffering from uremic syndromes, it was not possible to appreciate the above mentioned change. The sternal or lateral recumbency was observed in all

affected subjects, but not in the control group: therefore it is likely that these postures can express pain, even if mild. However, those dogs with an increased score pain remained for a long time in the same position or oppositely, changed position constantly. The vocalizations were associated only to severe pain, and in the control group, associated to fear or to attention withdrawl. A good percentile of dogs with a score that went from 3 to 6 (mostly belonging to Groups A and C), appeared to be as calm as subjects from the control group. This attitude, if associated to an average pain score, should lead to the suspicion of malaise. Moreover, most dogs showed to be reactive to active voices and nursing care. The more shy reactions, except for subjects with higher scores, were often associated to the character of the animals, as confirmed by the questionnaire of the owner and as noted in the control group. As far as the assessment with the dog walking outdoors on a leash, which was ideally constituted as a mean to free the animal from further anxieties and fears that are related to the movement in a closed environment, in our experience represented a confirmation of the results of those subjects that were free to roam in large kennels. During the clinical examination antalgic postures, specifically false kyphosis, were evident, of course, in patients with infectious gastroenteritis (associated with high scores) but also in some dogs with respiratory and urinary tract diseases (score 4-5), confirming the value of reliable indicators of acute pain of various intensities. Other parameters, such as heart and respiratory rate, were increased both in diseased subjects and in controls with respect to basal values: moreover, scores resulted to be higher in patients with acute gastro-intestinal and respiratory diseases.In hospitalized subjects, the possibility of serial repetitions of observations was useful to refine previous scores: by re-evaluating the animal several times, all operators tended to give higher scores than the initial ones.
With regard to the inter-operator variability, scores were almost superimposable in the 3 groups, although Group 1 always gave slightly higher scores than the other ones, which may be related to the student's less rational approach, but also to a prolonged contact established with animals, especially if hospitalized. In our experience, although limited, introduction of a combined approach, including not only a semi-objective assess as obtained from scales already validated, but also a behavioural observation and thorough clinical examination, allowed to recognize pain, also of slight entity, in disorders in which analgesics are rarely used. Such experience must however be improved by increasing the sample size and the number of diseases taken into account, and including both acute and chronic pathologies.

Schedule 2: questionnaire for the owners

UNIVERSITA' DEGLI STUDI DI PERUGIA
Dip. Patologia, Diagnostica e Clinica Veterinaria

dog's name: _____

reason for visit: _____

1) how many hours does your dog spend playing?
□ one □ two or more □ none

2) normally your dog sleeps:
□ curled □ belly up □ outstretched

3) your dog prefers food:
□ wet □ dry □ homemade

4) is it possibile to approach him/her while eating?
□ yes □ no

5) while walking your dog:
□ remains on a leash □ is free to walk around

5) how does your dog behave with other dogs?
□ in a friendly manner □ at first is suspicious then friendly □ is afraid □ is aggressive

6) how does your dog behave with strangers?
□ is friendly □ at first is suspicious then friendly □ is afraid □ is aggressive

7) does your dog spend time in environments different from your house?
□ yes, often □ sometimes □ rarely □ never

8) how does he/she behave in new environments?
□ curious, explores and sniffs everything □ shy and a bit scared, it takes a time to calm down
□ very scared □ I don't know

9) do you seperate from your dog?
□ yes □ yes, but there is always someone in the house □ no, I always bring him with me
□ sometimes he stays alone, but most of the time I bring him with me

10) When your dog is home alone:
□ he behaves well □ he destroys the furniture □ cries □ barks □ I don't know

11) when he is separated from you:
□ he behaves well □ he's unconfortable □ I don't know

12) when you take him/her to the veterinarian:
(tick more than one box)
□ he barks and moans □ he is frightened □ he's a little nervous
□ he's calm □ aggressive □ allows the vet to visit him/her
□ he reacts to manipulation of certain body areas (ears, eyes, feet) □ seeks for comforting
□ he/she doesn't let anyone touch him/her

12) How would you define your dogs behaviour?
□ very vivacious □ vivacious □ calm □ shy and fearful

TARGET CONTROLLED INFUSION (TCI) OF OPIOIDS: AN OVERVIEW

Corresponding author: Lorenzo Novello, e-mail: info@isvra.org

'One of the delights of anaesthesia is that the administrator of the drugs observes the nature and duration of the effects produced'.[1] To take most advantage of intravenous analgesics requires basic understanding of pharmacokinetics and pharmacodynamics. Pharmacokinetics (PK) is what the body does to the drug, i.e. the relationship between the dose administered and the concentration generated.

Pharmacodynamics (PD) is what the drug does to the body, i.e. the relationship between the concentration achieved and the effect generated. Therefore, a better understanding of the behaviour of intravenous drugs will help to achieve the desired effect in a more optimal way.

Compartment models are mathematical equations used to predict plasma concentrations of drugs based on experimental observations. In an experimental setting a drug is administered to a group of patients, and plasma concentration measured at different time intervals since administration. The mathematical equation that fits to data will be the compartment model describing the behaviour of the drug administered. Compartment models are an attempt to provide physiologic insight into the mathematical relationship between dose and concentration. With the probable exception of systemic clearance, there is little physiologic or anatomical 'truth' to the volumes and clearances identified in pharmacokinetic models.[2] Multi-compartment models account for the uptake of drugs by different tissues in the body, which depends from physicochemical properties of the drug being considered and blood flow rates to the above tissues. Tissue sharing pharmacokinetic properties form a compartment. Although the number of theoretical compartments is limitless, it is experimentally impossible to distinguish more than three compartments. The central compartment is the compartment in which the drug is administered and from which the drug distributes to the other compartments. Elimination occurs only from the central compartment, and is described by the elimination rate constant. An effect compartment, which is the compartment where the drug exerts its effect, can be added to these multi-compartment models, however it is so small that does not contribute to the total volume of distribution of the drug. The effect compartment is in equilibrium with the central compartment. Most drugs of major interest to anaesthesia/analgesia behave like two- or three-compartment models. In the two-compartment model there is a central compartment connected to a peripheral compartment. The volume of the central compartment is V_1, that of the peripheral one is V_2, and the total volume of distribution is the sum of these two volumes. Transfer among compartments are described by specific rate constants. PK and PD concepts can be used in a clinical setting to develop dosing regimens for achieving the desired effect in the desired time frame, quickly achieving and maintaining a constant effect, predicting when to stop an infusion to achieve the desired clinical recovery, etc. A constant drug concentration offers the advantage of a stable anaesthetic, due to lack of peaks and troughs which may result in side effects or insufficient anaesthesia and/or analgesia. This can be achieved manually using the BET method, first described by Kruger-Thiemer in 1968. The method relies on an initial bolus (B) to achieve the desired concentration, a continuous infusion to replace the drug that has been eliminated (E), and a decreasing infusion to replace the drug that is transferred (T) to peripheral tissues. The current target-controlled infusion (TCI) systems represent the evolution of the BET scheme. Using complex mathematical models a TCI software calculates the drug dosage to be infused in order to achieve and maintain a stable concentration over time. As a result, the infusion rate is updated frequently (up to 5-10 seconds) according to the prediction of the pharmacokinetic model. A TCI software can be used for simulation, allowing the clinician to manually set the infusion rate according to software prediction (Manual TCI), or can be connected to a syringe driver and used to deliver a TCI.

Modified BET schemes have been described for fentanyl in cats,[3,4,5] fentanyl in dogs,[6] and propofol in dogs.[7] In addition, propofol-fentanyl TCI has been prospectively compared to isoflurane balanced anaesthesia in dogs, and analgesic levels during ovariohysterectomy and spinal surgery propectively investigated.[8,9] Fentanyl TCI has already been reported successfully in dogs[10,11] and cats.[12-14]

Anecdotal evidence and current literature suggest that a large variety of drugs including opioids is commonly administered to small animals for analgesia. In humans intravenous administration of analgesics is common practice, and Target Controlled Infusion (TCI) is actually a well established technology that has been used for over 15 years.[15] In small animals, however, intravenous administration of analgesics is typically accomplished by manual bolus or constant rate infusion (CRI) since major veterinary anaesthesia books do not thoroughly discuss the delivery of intravenous drugs according to the drug's pharmacokinetic behaviour. Reports on the use of pharmacokinetic model-driven drug delivery in dogs and cats are therefore limited, and syringe pumps with optional TCI capabilities implementing small animal PK-PD models are not available.

Although in the clinical setting PK model-driven infusions may offer some advantages over constant rate infusions for perioperative antinociception and analgesia, no reports comparing these techniques in small animals are currently available. In humans, an overall preference of anaesthetists for propofol TCI when compared to manual infusion of propofol has been reported. In addition, TCI resulted in more rapid induction, greater degree of titration and lower incidence of patient movement during surgery.[16] A variable computer-assisted continuous infusion of fentanyl resulted in superior haemodynamic stability and fewer interventions with adjuvant anaesthesia or vasoactive drugs compared to constant infusion and multiple bolus doses.[17]

Recently, a survey reported on the use of PK model-driven infusion in small animal anaesthesia and analgesia in Italy.[18] Surprisingly, almost 50% of respondents used a PK model-driven infusion, and the majority of them believed that having access to pumps with TCI capability would improve practice and patient care. PK model-driven infusions were also perceived as increasing haemodynamic stability, requiring fewer interventions to adjust anaesthetic depth to surgical stimulation and providing more effective analgesia with less side effects compared to CRI and administration of bolus doses. Although TCI allowed much easier and faster titration, and resulted in greater satisfaction and confidence compared to manual infusion regimens (i.e. Manual-TCI, BET schemes), portability of current TCI systems was questioned, and technical problems causing infusion failure were reported.

In conclusion, PK model-driven infusions are likely to play a major role in the provision of effective analgesia in small animals, provided that veterinary TCI systems are available. Further study on pharmacokinetics and concentration-response characteristics of anaesthetic and analgesic drugs will increase TCI popularity among veterinary surgeons worldwide, and possibly help with the release of commercial TCI systems implementing small animal pharmacokinetic models.

MULTIMODAL SEDATION AND PAIN MANAGEMENT IN THE EQUINE DENTAL PATIENT

Elizabeth F Schilling DVM
College of Veterinary Medicine, Western University of Health Sciences,
309 E. 2nd St, Pomona, CA USA 91766

Abstract
Multi-modal and pre-emptive analgesia are terms that have become familiar to both human and small animal health care providers. It would seem logical that these principles should be equally emphasised in equine medicine and dentistry. However, outside of referral centres these approaches are not yet everyday concepts in equine practice.
One of the key concepts of multimodal analgesia is the use of multiple analgesics, most often belonging to different mechanistic classes, to achieve optimal analgesia with smaller doses of each agent, thus minimising the risk of adverse effects. Similarly, multimodal sedation is ideal for standing surgery and dental procedures. Use of a pre-emptive well-thought out approach can result in a better sedative experience with increased comfort and safety for the patient, veterinarian and handler. In human dentistry, it is noted that fear and anxiety have a role to play in the perception of discomfort or pain related to a dental visit[1]. Veterinary patients may not be able to verbalise anxiety relating to anticipation of a dental procedure, but this does not negate the fact that they likely perceive pain[2].
Multimodal analgesia has been widely addressed in the horse [3-6]. Analgesic modalities which are particularly useful in equine dentistry include local and regional anaesthesia, opioids, NSAIDs, Alpha-2 agonists, and acupuncture. Multimodal sedation, in conjunction with balanced analgesia, provides for a successful sedative experience while aiming to minimise adverse effects. A rational approach to planning sedation for equine dentistry includes: evaluation of the patient's temperament and level of training, assessment of the safety of the facilities, degree of existent pathology, and expected level of pain from the planned procedure.

Introduction
Regular dental care is an important aspect in maintaining the general health of equids[7-8] just as in any other species. It is hard to argue that appropriate pain management is an important part of treatment planning in human and small animal dental patients, and so it should be for equine patients as well. One major difference in equine dentistry is the need for standing sedation in order to safely and comfortably perform dental procedures. Human patients can understand and (it is hoped) comply with verbal explanations and requests, and in small animal dentistry general anaesthesia has become the standard for achieving a proper oral exam. In horses and other equids anaesthesia is more problematic vis-a vis dental procedures. Due to their size, general anaesthesia is inherently more risky in horses than in small animals, and complications are potentially severe (myositis, traumatic recovery, death)[9]. Additionally, it is physically very difficult to perform quality dental work on a recumbent equine patient. Therefore the quest for the perfect "standing sedation cocktail" is a large part of equine dental practice.
While a one-size-fits-all approach is likely to be effective most of the time, individual variation must be taken into account. In addition to the tremendous variety in size amongst the various breeds (80-800kg), there are differences in response to sedation between the breeds as well as among individuals within a given breed. Even during the course of a single horse's life, differences in handling, environment, and existent pathology or concurrent general disease can change its response to sedation.
Multimodal analgesia
It has been well recognised in human medicine that preemptive multimodal analgesia leads to a much better perioperative experience, decreased post-operative pain, and improved healing[10-15]. This knowledge has applied well to small animal medicine and surgery. In 2007 the American

Animal Hospital Association produced guidelines for pain management, which include recommendations for a multimodal approach[16]. It is becoming well known that these same principles apply equally well to the equine species[3, 5, 17-19].

Common complaints after equine dental procedures include pain in the masticatory muscles, unwillingness to eat, ptyalism, or quidding[20-21]. Some of these signs may relate to dentinal pain secondary to exposure of odontoblast processes after routine floating[1, 22] but the majority of post-procedural pain originates from the muscles of mastication and the temporomandibular joints, resulting from the forces applied against the full-mouth speculum employed to gain access to the horse's oral cavity. Given that quality dentistry requires full access to and visualisation of the oral structures, and therefore necessitates the use of a speculum, some degree of pain is anticipated and it is therefore logical to apply our knowledge of perioperative pain management in other species to the equid as well.

The primary pain pathways which concern us in equine dentistry involve the trigeminal nerve and the sensory nucleus of the trigeminal nerve in the medullary dorsal horn of the brainstem. Dental or oral pain may be due to a noxious stimuli, (acute dental disease or the dental procedure itself) inflammation, or may be neuropathic in nature, or the result of chronic disease[23]. The pulp is innervated by branches of the maxillary and mandibular alveolar nerves. Dental pulp contains both C and A-□ fibres, with C-fibres being more prevalent[1]. The masticatory muscles and oral soft tissues are likewise innervated by the trigeminal nerve. Proprioceptive information is also carried by the trigeminal nerve; so significant changes in occlusion may lead to potential post-procedural effects as well.

We have a variety of drugs available to effect analgesia at multiple points in the pain pathway. Local anaesthetics (regional blocks or local infiltration [24]), NSAIDs and opioids can prevent transduction of the nociceptive impulse. Alpha-2 adrenenoreceptor agonists, the most commonly used sedatives in equine practice, as well as local anaesthetics block transmission. Alpha-2 agonists, NSAIDs, opioids and NMDA antagonists can all effect modulation. Lastly, alpha-2 agonists, opioids, and general anaesthetics can be used to block perception of pain.

Local anaesthetics can block surgical pain, and reduce the need for post-operative analgesia[25]. Local infiltration[24] or regional blocks can both be effective in equine dentistry. A combination of lidocaine and bupivacaine is often used, to take advantage of both rapid onset of action and long duration of analgesia. In addition to submucosal infiltration, regional nerve blocks commonly used are the infraorbital (blocks incisors, canines, and 1-2 premolars), maxillary, mental (incisors and canines) and mandibular. Techniques are described elsewhere.

The most commonly used NSAIDs in the horse in the US are phenylbutazone and flunixin meglumine. A relatively new option is topical Diclofenac , which has some anecdotal support for use on TMJ pain and myofascial pain of the masseter muscles.

Opioids have been shown to be effective in the horse[26]. The most commonly used is butorphanol, a mixed agonist/antagonist. Most of the pure μ agonists are not commonly used in equids, in part because of increased record keeping requirements, and because of side effects such as ileus or an excitatory phase. Fear of post-operative complications such as ileus have not borne out. It is postulated that the difference in the effects seen in painful horses vs test subjects may simply be due to the fact that the patients needed the analgesic.[19]

Recently there has been investigation into the use of NMDA antagonists, gabapentin, tramadol etc in the horse, with some promising results. These drugs may quite possibly hold promise for dental cases, but have not been widely used at present. It is likely that their utility will rest more in the treatment of more chronic pain, but may be limited to in-hospital situations.

Multimodal sedation

The principles of multimodal analgesia apply equally to sedation. The goal is to obtain optimal sedation with minimal adverse side effects. Common side effects of sedatives in horses include cardiovascular effects, transient ataxia and decreased GI motility which may lead to impaction, choke or ileus[27-28]. These effects are dose-dependant so a multimodal strategy allowing lower

doses to be used is an appropriate approach. Combining analgesic and sedative plans allows for a truly multimodal approach.

Most important perhaps is the fact that a comfortable patient will require less sedation. Appropriate analgesia administered well before the initiation of any noxious stimulus will result in a quieter, less anxious patient. The other major factors in sedation of horses relate to handling and technique. The less habituated the horse is to being handled or restrained, and to new and different sounds, the more sedation is typically required to safely accomplish a procedure. A quiet and safe environment and calm confidant demeanour will help to lower the horse's anxiety. In addition, the use of anxiolytics or mild tranquilisers will decrease the amount of sedation needed. Acepromazine administered 15-20 minutes prior to any stimulation will help to ensure a quiet horse. Diazepam is another option, however its use should be limited to situation where the horse can be restrained in a stocks or in a solid corner, as it tends to produce moderate to severe although transient ataxia, which often results in a hyper-anxious patient.

The most commonly used sedatives in the horse are the alpha-2 agonists. Most veterinarians who routinely use a set "cocktail" base their sedation protocol on detomidine for its greater depth of sedation and longer duration. One common drawback to the use of detomidine alone is the ataxia it causes, an effect that often causes anxiety in the horseowner. Xylazine is often used alone for shorter procedures or "stacked" with detomidine in an attempt to achieve an intermediate level and duration of sedation. Romifidine, long used in Europe, has only recently been available in the US. Romifidine provides sedation and analgesia at a level similar to detomidine[25], but with less ataxia.

Fortunately for the equine dental practitioner, there is not only synergism but also some crossover effect between the alpha-2 agonists and opioids commonly used in horses. Alpha-2 agonists such as xylazine, romifidine, and detomidine provide a degree of analgesia as well as sedation. Similarly, while opioids such as butorphanol are primarily analgesic, there is a degree of sedation provided as well. The mu agonists have been reported to cause an excitatory phase, an unwanted effect in the standing horse. However, in a balanced protocol with sedatives, this is not seen[19, 29]. A balanced multimodal sedative and analgesic approach is exemplified by the use of anxiolytics, NSAIDs, opioids and alpha-2 agonists, and will result in a comfortable patient and a happy clinician.

In summary, this author's approach is as follows: First, examine the patient in a quiet setting. Particular attention is paid to heart rate and rhythm, core temperature, GI motility, the tractability of the patient and the presence of pain or pathology. Premedication is administered (usually a combination of acepromazine, butorphanol, flunixin and, in nervous patients, an Alpha-2 agonist). The patient is allowed to relax while equipment is set up or while the previous patient is worked on. After 15-20 minutes, the patient's level of anxiety is assessed and a small amount of an alpha-2 is administered. The speculum is applied and a comprehensive oral examination is completed. Some patients at this point will allow routine procedures, with roughly half the label dose of an alpha-2 agonist.

In cases of moderate or severe pre-existing pathology, or when a particularly painful or lengthy procedure is planned (radiography, extraction, periodontal treatment)regional nerve blocks may be administered, or a CRI may be used[30-31]. The CRI may be sedative only (detomidine), analgesic only (butorphanol or butophanol-lidocaine) or mixed (detomidine, butorphanol). Use of a pentafusion (Ketamine, lidocaine, morphine, acepromazine and detomidine) has been reported in laminitic horses;[19] its use may be worth investigating in treatment of some of the more chronic conditions such as EORTH. A welcome side effect of a lidocaine infusion in horses sedated with alpha-2 agonists and opioids is its prokinetic properties. There remain possibilities to be explored; tramadol and gabapentin may prove to be useful in equids. New combinations of analgesics may provide even better levels of analgesia, allowing for less sedation, comfortable patients, shorter recovery times, and satisfied clients.

PAIN MANAGEMENT OF GASTRIC DILATATION-VOLVOLUS SYNDROME IN DOGS

C. Filippi, DVM, PhD e-mail: claudia@aureliavet.com

Gastric Dilation-Volvolus GDV syndrome is a surgical and medical emergency bearing high mortality risk in dogs, even when treated. Predisposing factors that may significantly increase the risk of GDV in dogs include breed, sex, age, feeding habits and patient temperament. In fact, large, brachicephalic or deep-chested breeds, male gender, aging, large volumes of food per meal, one meal for day, voracious eating and anxious temperament, favour and add their specific problems to GDV syndrome.

Clinical presentation includes pain and discomfort hinted by suffering "facies", arched back, dyspnoea, restlessness due to abdominal distension, non productive vomiting, hyper salivation, signs of shock such as tachycardia, weak pulse, crt > 2'', pale mucous membranes. Clinical findings depend on severity of shock.

Treatment priority must be given to symptomatic shock therapy to stabilize patient conditions. Gastric decompression must be performed rapidly, in fact compression of caudal vena cava and portal vein by the dilated and/or rotated stomach reduces venous return and cardiac output. Hypovolemic shock and gastric necrosis may lead to systemic inflammatory response syndrome (SIRS), multiple organ failure (MODS) and disseminated intravascular coagulation (DIC) (2).

Shock therapy includes oxygen and fluid-therapy. Crystalloid solutions are administrated trough two large bore IV catheters, while the choice of solution depends on results of blood-work (high PVC, low TS) and blood-gas analysis (metabolic acidosis and electrolyte imbalances). Monitoring of vital signs, blood pressure and cardiac activity should be performed during shock therapy. In fact, and inadequate tissue perfusion leads to multiple organ failure. Metabolic acidosis promotes cardiac arrhythmias also associated with gastric necrosis. Ventricular arrhythmias, DIC and reperfusion injury are the most common cause of increased mortality also in the postoperative period (2).

Gastric decompression can often be performed by gastric tube in case of dilation or incomplete rotation, while gatrocentesis may be the only choice for relieving distension in case of gastric torsion.

Pain, due to stomach wall necrosys and systemic derangement, is classified as "deep visceral pain" characterized by autonomic signs. Such pain worsens patient clinical conditions by promoting acetylcholine and catecholamine release, dyspnoea and cardiac arrhythmias all reducing patient's response to shock therapy. Unfortunately such critical scenario does reduce the choice of analgesic drugs, precluding the administration of Non Steroidal Anti Inflammatory Drugs (NSAIDS) due to their effects on gastric secretion and on renal perfusion already compromised by the shock. Alpha-2 agonists too are contraindicated due to their negative cardiovascular effects impairing peripheral perfusion and cardiac work. Under these circumstances, opioids are the best analgesic option, due to their powerful effect, their ability to spare cardiac performance and possibility of reversing them. Their administration should be started along with shock therapy and gastric decompression. First choice opioids are Methadone, Buthorphanol and Fentanyl, but Buprenorphine, Meperidine and Morphine can be reasonable alternatives in expert hands, under oxygen supplementation. If opioids are not available, Tramadol can be a choice. When surgical correction is indicated, general anaesthesia is mandatory in spite of the ASA 4^{th} or 5^{th} risk class. To stabilize the haemodynamic conditions can require a total of 60-90 ml/kg fluids loading dose.

A short acting hypnotic and/or Fentanyl/benzodiazepine induction are first choice options for anaethetic induction. The use of a ketamine/benzodiazepine combination fot induction is also a widespread reasonable alternative, followed by inhalation anaesthesia.

Before anaesthetic induction, a loading dose and a CRI of Fentanyl should be started to allow for surgical analgesia and to benefit from its anaesthetic sparing effect. A very good alternative to Fentanyl is provided by a CRI of Lidocaine, also to be commenced before surgery and after a loading dose.

Once surgery is over, recovery can be complicated by a number of life threatening conditions including pain, sepsis, shock, hypotension, hyperkalemia, or acute kidney and/or liver failure. Since analgesia must be continued, Naloxone should not be administered at this time to avoid full opioid antagonism, relying on Buprenorphine or Buthorphanolo to provide long lasting analgesia without severe respiratory depression. Due to their considerable latency, such opioids should be injected 20 – 30 minutes before the end of anaesthesia. If Lidocaine by CRI was administered during anaesthetic maintenance, it is wise to continue such infusion, allowing for its antiarrhythmic and anti-inflammatory effects, also effective to prevent reperfusion injury. To provide long lasting profound analgesia, Fentanyl patches are also a good choice.
Postoperative respiratory monitoring and oxygen supplementation, along with cardiovascular, urinary and acid-base monitoring are compulsory during the first twelve hours In a later recovery phase the analgesic regimen should be lessened by reducing drug dosages without prolonging their interval above their reported half-life. Such analgesic sparing must be accomplished without patient suffering, for humane as well as for clinical reasons grounded on negative consequences of pain in such compromised patients.

VALUE OF LOCAL ANAESTHESIA AS MEANS OF PRE-EMPTIVE ANALGESIA IN SMALL ANIMAL SURGERY

Bruna Santangelo

Department of Clinical Veterinary Sciences, School of Veterinary Medicine, University of Naples Federico II
Corresponding authors: bruna.santangelo@alice.it

The goal of peri-operative pain management is to reduce pain and speed recovery while minimizing complications originated from the analgesic technique. Preemptive analgesia, an evolving clinical practice, entails the administration of an analgesic regimen before the onset of noxious stimuli, with the aim of preventing central nervous system sensitization to subsequent stimuli which would amplify pain [1].
Surgical pain results from local tissue injury, peripheral responses and central nervous system sensitization. Local anaesthetics, by blocking nerve transmission to central nervous system, can prevent the establishment of central hyper-excitability thus reducing or eliminating pain enhancement due to post-operative sensitization [2]. Further to this, local anaesthesia provides superior pain relief, powerful anaesthetic sparing effect, faster post-operative recovery and reduced patient hospitalization compared to systemic analgesic treatments [2,3].
Local anaesthetics have been used for more than a century for analgesia in humans and animal medicine and are generally considered safe and effective for producing complete local and regional desensitization. In veterinary medicine, local anaesthesia has been used in most species for pain therapy, as well as for diagnostic purposes primarily in the equines [1].
Several different techniques are used for blocking nervous transmission from a surgical field, including central blocks (epidural and spinal anaesthesia) and peripheral local anaesthesia such as nerve, splash, ring, line and joint blocks [3].
Until recently, loco-regional anaesthetic techniques for controlling pain in small animal hind limb surgery have been confined to the neuraxial approach, in spite of a lower incidence of post-operative complications reported for peripheral nerve blocks [4, 5].
In veterinary medicine peripheral nerve blocks are still typically performed using anatomical landmarks for nerve location, while the use of peripheral nerve stimulators allows for more accurate needle placement relative to the nerve to be blocked, reducing the risk of nerve damage or technique failure. Such devices consist of a constant-current generator joined to an insulated exploring needle and a remote ground lead connected to the skin. The stimulating needle is also connected to an injection port allowing precise drug deposition next to the identified nerve.
The nerve stimulator produces motor responses whose strength depends on the current intensity and on the distance between nerve and needle. The key rule is that evident muscular contractions following a low-intensity current stimulation indicate that the tip of the needle is very close to the nerve trunk [6, 7].
When the initial motor contractions of the muscles dependent from the stimulated nerve appear, the current is slowly decreased in amperage while the needle tip is slowly advanced toward the nerve. Persistence of motor response at 0.2 mA indicates risk of intraneural injection which may cause nerve injury [7].
Brachial Plexus Block (BPB) provides front limb analgesia and paralysis distal to the elbow, by blocking radial, median, ulnar, musculocutaneous, and axillar nerves [3]. The BPB puncture spot is located at the level of the scapulo-humeral joint in a plane medial to the scapula. The needle direction must be caudad, aiming toward the costo-chondral junctions and, once BP is located, the anaesthetic solution is spread on a wide area while retracting the needle. Due to the high vascularity of the area and the potential for inadvertent intravascular injection, frequent aspiration and slow injection is recommended [5]. An alternative technique is provided by selective median, ulnar,

musculocutaneous, and radial (MUMR) nerve blocks to desensitize structures distal to the elbow [3].
Hind leg local anaesthesia distal to the hip can be achieved by selective blocks of the saphenous, common peroneal and tibial nerves, while analgesia of whole hemi-pelvis can be achieved by blocking the ipsilateral sciatic and femoral nerves (lumbar plexus) [2, 5, 6]. A nerve stimulator is particularly helpful for these kind of blocks. The puncture site for the proximal sciatic nerve block is located at one-third of the distance along a line that joins the femoral greater trocanter and the ischiatic tuberosity, closer to the greater trocanter. Needle insertion is perpendicular to skin surface. A correct nerve stimulation produces foot dorsiflexion (peroneal component) or plantar flexion (tibial component) applying a stimulating current of 0.5 mA [5].
To achieve lumbar plexus block, the puncture site is located 1-2 cm lateral to the midline, at level of the L5 vertebral body. The stimulating needle is advanced ventrally, parallel to the sagittal plane with a slightly caudal direction, until a femoral nerve response is elicited, proved by contractions of the quadriceps muscle associated to leg extension [5, 8]. Tacking the same precautions as for the brachial plexus block, the selected volume of anaesthetic solution should slowly be delivered.
Local anaesthetic action and duration depend on drug concentration and on a critical drug volume delivered to achieve a lasting nerve minimal exposure length [8].
According to Campoy et al. (2008), by the accurate use of a peripheral nerve stimulator, a volume of 0.3 ml/kg should be sufficient to produce a brachial plexus block in dogs, while volumes of 0.05 ml/kg and 0.4 ml/kg would be adequate for sciatic nerve and lumbar plexus blocks respectively [8].
Dependent on the specific anaesthetic molecule and concentration, local block duration changes from 2 to 8 hours. The long-acting local anaesthetic molecules produce smooth recovery and less postoperative pain.
Lidocaine and Bupivacaine.are the most popular local agents in dogs. A Lidocaine dose of 2–6 mg/kg provides an effect lasting 1–2 hours with a short latency. The dose for Bupivacaine in dogs is 1–3 mg/kg with a delayed onset (30 minutes) and a 4–8 hours lasting effect [3].
Few reports on the clinical use of Levobupivacaine and Ropivacaine exist in small animal's literature, although these newer long-acting agents present a potentially wider safety margin [9], lower cardio- and neuro-toxicity compared to bupivacaine [9, 10], provide a similar dose-dependent sensitive block with a shorter duration of the motor block [11, 12, 13].
The value of peripheral nerve blocks has been well established in humans, often in conjunction with other drugs and techniques for a balanced approach to surgical anaesthesia and post-operative analgesia. We support these techniques for small animal preemptive analgesia along with general anaesthesia and as part of multimodal analgesia because they are effective, safe, easy to perform and inexpensive. Due to their anaesthetic sparing effect, nerve blocks allow for intra-operative reduced anaesthetic depth, while the cardiovascular, respiratory, urinary and gastrointestinal side effects of other post-operative analgesics can be reduced or eliminated through the incorporation of peripheral nerve blocks in a multimodal approach [1].

LIDOCAINE CONSTANT RATE INFUSION FOR SURGICAL ANALGESIA IN DOGS

Filippi C[1], Ricco A[2], Belli A[3], Cordella C[3], Marino F[3], Reynaud F[3], Vesce G

[1]DVM, Ph D, Rome, Italy; [2]DVM, Ph D, Battipaglia, Italy; [3]Department of Clinical Veterinary Sciences, School of Veterinary Medicine, University Federico II, Naples

Lidocaine (L) is a local anaesthetic agent also used for its antiarrhythmic, central analgesic and anti-inflammatory properties.
As a local anesthetic L is administered by topical application, tissue infiltration, nerve and plexic blocks, paravertebral, spinal and epidural analgesia an Bier block.
As an antiarrhythmic, Lidocaine hydrochloride is highly effective against ventricular arrhythmias, although studies in dogs demonstrated the ability of this molecule to act also on supraventricular arrhythmias (David et all. 1990).
In humans too Lidocaine is used to treat ventricular arrhythmias even in the course of myocardial infarction, to control tachycardia and to prevent reflex hypertension during laryngoscopy and endotracheal intubation.
In dogs Lidocaine is used intravenously to treat most tachyarrhythmia, including those produced by sodium Thiopental and halogenated anaesthetics during general anesthesia, as well as during cardiac surgery, gastric torsion, and other life threatening conditions. In small animals CPR, Lidocaine is used as means of chemical defibrillation and to reduce the recurrence of post resuscitation ventricular arrhythmias (Paddleford and Short 1973). Moreover, an hypnotic potential of L has been reported in experimental as well as in clinical circumstances (Hirota et al. - 2000; Muir et al. - 2003), to produce a thiopental sparing effect and to ease endotracheal intubation by direct action on laryngeal and pharyngeal reflexes (Björling DE, et al. 1982).
Recent studies (Cassuto, 2003) highlighted the ability of Lidocaine to act as an antioxidant and in modulating the inflammatory response, suggesting its use to prevent the consequences of post-ischemic reperfusion, systemic inflammatory response syndrome (SIRS) and multiple dysfunction syndrome organ (MODS).
The central mechanisms by which Lidocaine reduces pain, although not clear, include also an interaction with μ and κ opioid receptors (Hirota et al. - 2000). A study by Ferrante et al. (1996) demonstrated the analgesic effect of IV Lidocaine for the treatment of neuropathic pain. Similar effects were reported in rats by L. CRI started 24 h before sciatic nerve ligation (Smith et. Al.2002).
Systemic administration of Lidocaine is a well-known support for the treatment of intra- and post-operative pain in dogs (Melanie, 2002; Smith, 2004; Ravasio, 2005). Such valuable analgesic effect is highly desirable in high-risk patients which may endure excessive cardiovascular depression from inhalation anaesthesia unless balanced anesthesia is provided. Under these circumstances systemic Lidocaine may directly improve patient cardiovascular stability while lessening cardiovascular depression by reducing inhalant agent requirements during painful procedures.
Muir et al. (2003) reported a 29% reduction of isoflurane requirements in dogs by administering a Lidocaine CRI at a rate of 50 μg/kg/min. Paulo V. M. Steagall et al. (2006) compared in dogs the Isoflurane sparing effects of Lidocaine with those of fentanyl during surgery, reporting a greater Isoflurane sparing effect of fentanyl (54-66%) compared to Lidocaine (34-44%). On the other hand, the Authors observed that "the low heart rate induced by fentanyl may partially offset the improvement in mean arterial pressure that would be expected with reduced Isoflurane requirements".
At the recommended doses, I.V. Lidocaine has minimal effect on heart rate in dogs. While its cardiotoxicity would reduce heart rate, coronary blood flow and myocardial oxygen consumption, it can ooccasionally produce sinus tachycardia secondary to peripheral vasodilatation (Singh, BN et all. 1978).
Adverse reactions associated with administration of Lidocaine at therapeutic doses (plasma

concentrations of 2-7 mcg/ml) are quite rare. When its serum concentration exceed 7 mcg/ml, the observed side effects include vomiting, neurological, cardiovascular and respiratory effects, namely drowsiness, agitation, decreased hearing, disorientation, muscle tremors, convulsions, bradycardia, hypotension, decreased QT interval and respiratory arrest (Heissenbuttler and Bigger, 1969). These symptoms require immediate correction of the infusion rate and symptomatic therapy.

At the Veterinary School of the University of Naples we have a fairly long experience with the CRI of Lidocaine in dogs, mainly for peri-operative analgesia in surgical patients. In our experience, the high safety margin and analgesic power of this drug is a strong indication for patients with a high anesthetic risk. We studied the effects of different infusion rates ranging from 50 to 200 mcg/kg/min, following loading doses of one to two mg/kg. In such studies we never observed significant changes in heart rate, recording rather an improved hearth rhythm by ECG, linked to the well known direct action of Lidocaine on cardiac cells. Recovery from anesthesia after Lidocaine CRI has always been smooth in our patients, without side effects ascribable to this molecule. We recorded a tangible long lasting post-operative analgesia persisting long after drug administration.

One of our studies (A.Ricco et al, 2005), was run on 16 dogs undergoing surgery to investigate, after a 1 mg/kg loading dose, the Thiopental and Isoflurane sparing effects of two (50 and 100 mcg/kg/min) CRI regimens of IV Lidocaine, along with the cardiovascular and respiratory and postoperative analgesic effects. This study proved the safety of our protocols failing to observe significant as well as the reported Thiopental sparing effect. In fact in our patients the cardiovascular parameters were in the normal range, while the postoperative pain score was obviously low in both groups.

In another study (A.Belli et al, 2009) we compared the analgesic and hypnotic effects of higher CRI dose regimens (100 and 200 mcg/kg/min) after a loading dose of 2 mg/kg, sampling our patients for serum Lidocaine and its metabolites concentrations. None of the patients showed signs of toxicity, nor side effects of note, while the Isoflurane sparing effect and postoperative analgesia were evidently dose related. In this study Lidocaine pharmacokinetics revealed blood concentrations within the therapeutic range, gradually declining during the CRI at 100 mcg/kg/min. Plasma concentrations found in patients receiving 200 mcg/kg/min stayed quite steady, also within the Lidocaine therapeutic range. In both groups we failed to observe bradycardia and hypotension which could have been offset by the lower Isoflurane concentrations. Such interpretation explained the apparent paradox observed in this study, where the average blood pressure and heart rate were significantly higher in subjects treated with 200 mcg/kg/min, compared with the lower dose group. We also observed that plasma concentrations of Lidocaine and its active metabolite MEGX decline quite slowly at the end of the CRI, with high individual variability in our patients. Presently, in clinical setting the most widely used protocol in our practice is a Lidocaine CRI of 100 mcg/kg/min following a loading dose of 1mg/kg. Patient selection for such analgesic treatment tends to exclude subjects with metabolic impairment.

We recommend Lidocaine CRI as a mean of multimodal analgesia in dogs undergoing surgery, particularly in those bearing a high anaesthetic risk.

vetpain@gmail.com

Introduction

Preventing, assessing and managing post-operative pain (POP) is essential in veterinary practice and should be a fundamental part of the quality care we must offer to sane or ill patients, in particular when the veterinary interest is aimed to surgery of dogs and cats, the two most human-linked companion animals. POP treatment is a need for reducing suffering, but also for improving recovery from anaesthesia and lessening surgery secondary effects (such as loss of appetite or self-trauma) which can prolong the time needed for healing from surgical acts itself or from primary lesion. Untreated POP decreases every time quality of life in all patients and pain, considered as the fourth main vital sign to monitor together with pulse, respiration and temperature, should be integrated into all post-surgical evaluations. Unfortunately, even if POP in companion animals is well known in its genesis, it can be frequently difficult to be exactly assessed in its intensity and degree and, consequently, faced in a proper way, avoiding over or under-treatment. Understanding and managing POP requires looking for mute signs and asking for right questions at the right moment, considering specific ethological characteristics and behaviour alterations, more than only trusting on physiological measurable parameters. Many dogs and cats may not show obvious indications of pain and identifying the amount of suffering associated with POP can be a challenge. Considering this, it is reasonable to assume that the evaluation of POP and the level of its treatment in companion animals will depend largely on the kind of attitude veterinarians have toward pain issues and on the knowledge base, related to general pain recognition and control. In evaluating and treating POP, great importance goes to the attitude of veterinarians toward some factors such as how much pain they think dogs and cats likely experience postoperatively, after different surgical procedures; how do they assess and measure POP in practice; which are their habits and concerns about analgesic agents usage or how do they gain information and updates on pain issue. These attitudes have been already investigated among veterinarians in Australia [18], Canada [5,6,9,10], Finland [16], France [11], New Zealand [20], South Africa [12,13], UK [2,14] and USA [7,15]. Similar surveys have been conducted also among vet-technicians and vet-nurses in Canada [4], UK [3] and USA [1,8], among vet students in USA [8] and even among small animal owners in Finland [17] while few is known about Italy. There are only anecdotal informations regarding the real attitudes of Italian veterinarians toward pain in companion animals and the way POP is recognized, evaluated and treated in private veterinary practices in Italy, with the only good exception of a recent graduation thesis presented at Perugia University [21].

Materials and methods

The primary purpose of the present study was to determine the attitudes of Italian veterinarians toward postoperative pain in companion animals; to collect data we used a survey, submitted to participants with an electronic questionnaire (EQ).

A survey is a simple data collection tool for carrying out research, capable of obtaining information with questionnaires, presented to large samples of population, useful to describe what exists, in what amount, and in what context and also good to establish baselines against which future or transnational comparisons can be made. Questionnaires are usually administered through the classical "paper and pencil" version, with face-to-face or telephone interviews, or submitted via postal mail. Considering the increasing use of the World Wide Web, not only to present and offer, but also to collect information about the characteristics, actions or opinions of large groups of

people, we chose an electronic option for our research, so offering an illustration of how survey data of this kind can actually be gathered among Italian veterinarians via internet and e-mail. We used an electronic option also for its economical advantage and for privacy concerns: this kind of survey requires in fact minimum resources (staff, time and cost) and is best suited to eliciting confidential information. Moreover, EQs allow the respondent the greatest latitude in time, pace and sequence of response and can cause minimal interviewer and respondent measurement errors due to the absence of a personal direct contact. However we must admit that, using EQs, bias may occur, either in the form of non-response error from participants (since some questions may be inadvertently or intentionally skipped) or in the nature and accuracy of the responses that are received. Intentional misreporting of behaviours by respondents (to confound the survey results or to hide inappropriate behaviour) are such types of error and bias may occur also when the intended respondent refers to others in completing the survey. It is also important to remember that all kinds of survey do not provide exact measurements of true populations, but only estimates, since they are subject to coverage error when population lists are incomplete or out of date.

Our independent veterinary study group, called "VETPETPAIN" (VPP) - founded in 2009, with the participation of some Italian private practitioners from the provinces of Brescia, Bergamo and Rome and with the support of CeSDA (Animal Pain Study Centre) of Perugia -, started the present study in January 2009. An EQ was constructed after a review of similar ones, submitted to veterinarians in other nations [2,5,6,9-14,16,20] but conducted in those cases using only paper documents. After ten trial interviews, sent via email to veterinarians resident in Brescia and Bergamo provinces, we widened the research to all Italian provinces. Our EQ was set up with free-ware programs, used to create and share web pages ("Google sites"™) or to upload, edit and store files and documents ("Google docs"™) and was submitted to participants exclusively through VPP Internet site, with on-line forms. In contacting all the 27442 veterinarians officially registered at FNOVI (National Federation of Italian Veterinary Provincial Boards), we faced the problem of the unavailability of their e-mail addresses: since a complete public email directory, useful to contact all veterinarians, isn't obtainable in Italy, we sent e-mail with a presentation file to the 103 Italian Veterinary Provincial Boards, asking them to act as "sponsors" for our research. Every Board (considering also legal concerns on privacy) was asked to communicate VPP web URL to all its members (either to their electronic or postal address) or to publish a direct link to VPP web main page (http://sites.google.com/site/vetpetpain/) on its own Internet site or through its electronic newsletter. On VPP site we presented the activity of our group and gave the link to fill in the EQ, asking for a volunteer participation only to those veterinarians effectively involved in companion animals surgery and involved in POP prevention, recognition, evaluation and relief. Our interest was to survey just this category of veterinarians, but there was however no actual way to previously sort out the recipients or to address only these colleagues, discerning them from all the other veterinarians registered in Italy but interested in different activities. However, on VPP site, we offered through a single preliminary "pain interest" question, the possibility to all connected veterinarians to express their effective interest in pain issues, even without filling the complete EQ. The veterinarians interested in participating the survey, found on VPP site the link to the EQ, divided into seven parts, with a first form asking 10 questions on biographical and professional anonymous data and other six forms to be completed with 30 questions on pain issues:

- INTEREST IN PAIN AND IN THIS SURVEY - PRELIMINARY QUESTION
- FORM 1) ANAGRAPHICAL AND PROFESSIONAL DATA - 10 questions
- FORM 2) INTEREST IN PAIN MANAGEMENT - 7 questions
- FORM 3) EVALUATION OF POP IN DOG - 2 questions
- FORM 4) EVALUATION OF POP IN CAT - 2 questions
- FORM 5) RECOGNITION AND ASSESSMENT OF POP - 2 questions
- FORM 6) USE OF DRUGS FOR POP TREATMENT - 14 questions
- FORM 7) KNOWLEDGE ACQUISITION AND UPDATE - 3 questions

In these forms, all linkable from VPP site, veterinarians found closed-end, partially closed-end or

open-end questions. With the first two kinds of questions the respondent was required to compare possible different responses and select one or more among them (or choose "other" to freely express a not already given answer), with choices ordered to form a continuum or with unordered multiple choices. In this case the respondent was given a full comprehensive selection of responses to choose from, while, on the opposite, the open-end questions gave the respondents the opportunity to express their own opinion, with empty line to fill with answer. After completion, each form was returned to VPP central database via Internet, in an anonymous and automatic way.

Results

Using a free-ware Internet statistic program ("ShinyStat™ Free" - http://www.shinystat.com/it), we could collect data on visits to VPP site, which summarized to 543 visitors during the period January 2009 – April 2010, mostly during Mondays (25%), in the hours between 5 and 6 PM (16%). Most parts of the contacts were made using Explorer Microsoft (51%) and a Windows OS (94%).

For the preliminary question we obtained 210 answers, with 195 veterinarians (93%) from 16 Provincial Boards, which declared themselves interested in pain issue and in participating to this survey, even if the actual number of respondents was lower, varying among different forms and different questions. Most answers were provided by veterinarians from Milan (42,1%), Bergamo (11,3%) and Brescia (6,2%) provinces.

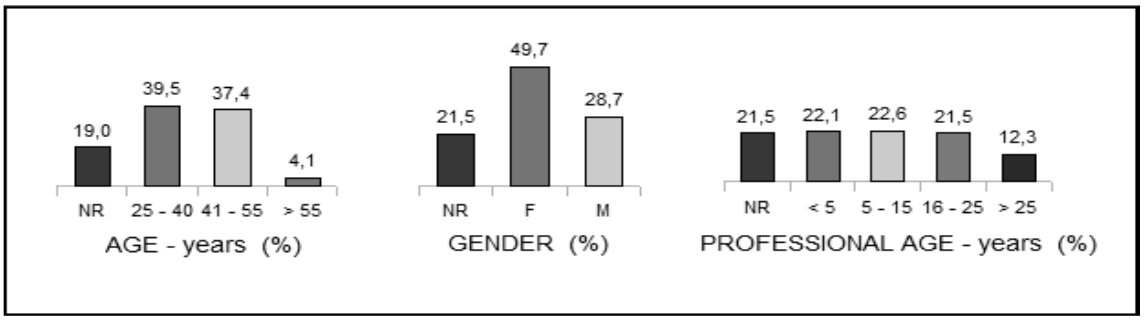

Figure 1. Biographical data of veterinarians responding FORM 1 of the survey

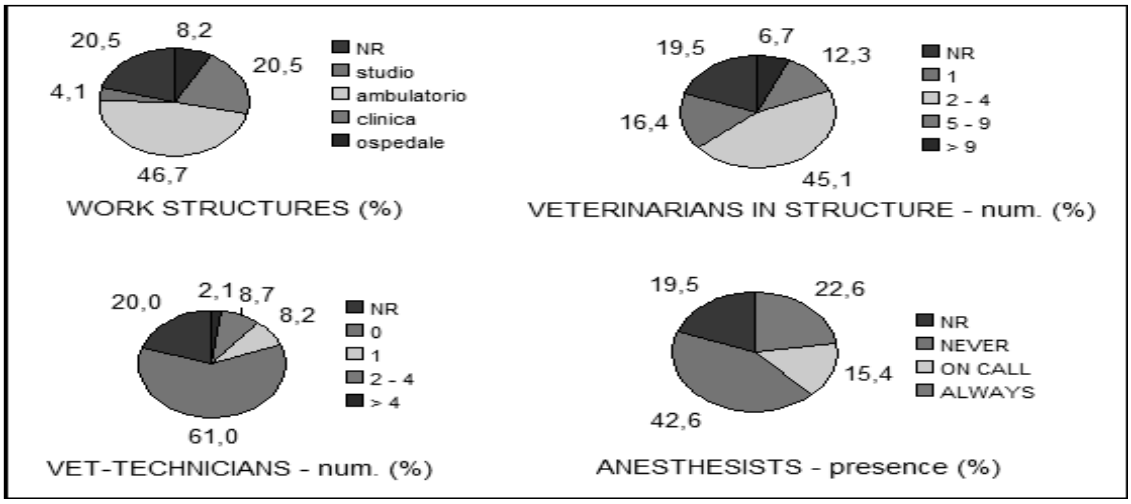

Figure 2. Professional data of veterinarians responding FORM 1 of the survey

Biographical data (age; gender; professional age) and professional data (size of the place of work; number of veterinarians, technicians and presence of anaesthetists in the structure) of veterinarians responding form 1 are shown in Figure 1 and 2, while some of the preliminary results of this still ongoing survey, updated after 15 months of data collection, are here exposed, expressed as percentage and summarized in tables 1 – 12.

Table 1. Questions 1 and 2 of FORM 2

It's important to treat POP in …	dog	cat
- very important	59,5	61,1
- quite important	11,3	9,7
- a little	1,0	1,0
- no	0	0
- NR	28,2	28,2

Table 2. Question 3 of FORM 2

Which one, among these statements, best depicts your working reality ?	%
"I'm sufficiently able to identify and evaluate POP"	30,8
"I'm not adeguately prepared to identify and evaluate POP and I would like to improve my skills "	21,0
NR	48,2
"I consider adeguate my knowledge about POP pharmacologycal theraphy"	24,6
"I don't consider adeguate my knowledge about POP pharmacologycal theraphy and I would like to improve it"	27,7
NR	47,7
"I think that POP identify and treat protocols in use in the structure were I work, are adeguate"	28,7
"I would like to change POP protocols in the structure where I work"	26,7
NR	44,6

Table 3. Question 1 of FORMS 3 and 4

How do you judge POP assessing in ...	dog	cat
- quite easy	48,2	9,1
- quite uneasy	51,8	54,5
- NR		36,4
- easier then in dog		3,0
- uneasier then in dog		90,9
- the same as in dog		3,0
- NR		3,1

Table 4. Question 2 of FORMS 3 and 4

Give a numeric value 1 to 10 to the POP intensity of these surgical procedures in ... (minimal = 1 / maximal = 10)	dog	cat
- ovariohysterectomy	6,5	6,3
- other abdominal surgery	6,9	6,8
- orthopaedics and traumatology	7,4	7,4
- mammal surgery	8,9	8,5
- perineal and perianal surgery	8,1	7,9
- eye surgery	7,7	7,7
- nose and ear surgery	8,1	8,0
- dental procedures	6,7	6,8
- thoracic surgery	8,4	8,4
OVERALL POP MEDIUM VALUE	7,64	7,53

Table 5. Question 1 of FORM 5

Which kind of alteration you consider first in your method of POP recognition ?	%
- physiological parameters and appetite	24,6
- behavior	18,6
- posture	18,3
- movement	17,0
- wound palpation response	11,2
- vocalizations	10,1
- other	0,2

Table 6. Question 2 of FORM 5

Do you use any scale to assess pain ?	%
- I use personal methods	47,1
- Glasgow p.s.	8,3
- Colorado p.s.	1,9
- Melbourne p.s.	1,5
- don't know any p.s.	30,1
- I use other p.s.	6,8
- I don't asess pain	4,4

Table 7. Question 1 of FORM 6

How often do you use drugs for POP treatment ?	%
- always	55,4
- frequently	38,8
- rarely	5,8
- never	0

Table 8. Question 2 of FORM 6

Why would you use antalgic drugs in treating POP ?	%
- to reduce post surgical pain and improve recovery	53,6
- for ethical reason	27,0
- to do surgery more quietly	14,4
- other	5,0

Table 9. Question 3 of FORM 6

Why would you never or rarely use antalgic drugs in treating POP ?	%
- I don't need to use drugs to treat POP for my surgery	22,3
- I'm afraid of side effects	12,2
- I don't know how to use drugs for POP treatment	10,8
- I have difficulties in pain assessment	10,1
- feeling POP limits movement and promotes healing	4,3
- other and NR	40,3

Table 10. Question 9 and 10 of FORM 6

The most used opiate in … ?	dog	cat
- fentanyl	22,7	15,8
- butorphanol	18,6	22,3
- buprenorphin	18,6	19,3
- tramadol	7,3	6,4
- others	23,6	21,3
I don't use opiates	9,1	14,9

Table 11. Question 2 of FORM 7

How would you like to update and deep your present knowledge about pain in animals ?	%
- through courses on-line	35,8
- with full immersion short courses	31,3
- with long time courses	17,9
- other	15,0

Table 12. Question 3 of FORM 7

Who would you like to take care of your continuing education in updating your knowledge about pain in animals ?	%
- National veterinarians society	33,6
- Provincial Veterinary Boards	31,3
- University	16,4
- other	18,7

Discussion

This paper presents preliminary results of a still running survey. From the data obtained until now, it's possible to assume that the analysed sample of Italian veterinarians, interested in surgery of companion animals, shows a fair attitude to identify, assess and treat POP in its patients. In fact, from the data showed in previous tables, we can infer that, in general, Italian veterinarians:

5- consider very important to treat POP;
6- think of themselves as "sufficiently able to identify and evaluate POP", using "adequate protocols" in doing it, but with a willing to improve their knowledge about POP pharmacological therapy, which they consider as "not adequate";
7- consider however "uneasy" to assess POP in companion animals, with assessment in cats more difficult than in dogs, a species that they think can have a higher POP intensity value;
8- repute alteration in physiological parameters and behaviour as the first facts to be looked at in POP recognition, using their own "personal methods" to evaluate POP, with a low knowledge of any validated pain scales;
9- tend to always use drugs for POP treatment, more for aiming at "reduce post-surgical pain and improve recovery" than for any other reason, with a preference, in the opiates class, for fentanyl in dogs and butorphanol in cats;
10- would like to update their knowledge on pain issue, via courses on-line or with full-immersion short courses, held by "national veterinarians associations" or Veterinary Provincial Boards.

It will be however necessary, in order to complete our study and give statistical validation and reliable interest to our data elaboration, to:

7- collect more responses from Italian veterinarians, also to make possible a confrontation

among diverse regional reality (north, centre and south Italy) and with analogous surveys made in other nations;

8- identify the statistics that could be used to relate variables or compare groups and provide evidence either in support or in refutation of the preliminary data already obtained.

Note: The forms of our EQ are still in actual use and so they will stay until the end of 2010; if you are an Italian veterinarian interested in small animal surgery and POP, you may respond anonymously as a participant, connecting to VPP site.

A substantial part of the studies designed to explain the physiological basis of acupuncture have been involved with pain assessment. Acupuncture induced hypoalgesia can be sufficient for certain surgical procedures and is very useful for treatment of pain originating from a variety of disorders [1].

Acupuncture action appears to be related to a combination of neurological and humoral mechanisms [2,3]. The acupuncture meridians usually follow the main nerves and acupoints are closely related to the nerve branches. Acupuncture analgesia fails to develop after local anaesthetic infiltration, nerve block of the nerves enervating the site of the needle application, spinal block or nerve section proximal to the point, implying a dependence on peripheral sensory receptors [3].

Acupuncture stimuli from the peripheral nerve may affect many sites in the central nervous system, both spinal and supra spinal, implicating an intricate pain complex in the CNS [4,5].

Studies have indicated that central serotonin, endogenous opioids, glycine and acetylcholine seem to be the most important substrates for mediation of acupuncture analgesia, while GABA, dopamine and substance P could act either inhibiting or stimulating according the region of the CNS involved, and catecholamines, especially norepinephrine, through alpha receptors, might exert an antagonist effect [2,5].

A humoral mechanism is involved in the acupuncture effect, because electroacupuncture analgesia can be induced in animals not needled, but cross-perfused with animals submitted to acupuncture [3]. In rats, rabbits, dogs and monkeys, administration of cerebrospinal fluid, serum or blood from animals submitted to acupuncture analgesia, produced analgesia in the receptors [6].

Endogenous opioids play a significant role in the humoral component of acupuncture-induced analgesia. Opioids are a significant component in mice, rats, sheep, horses and primates, including man [7].

There is increasing evidence that acupuncture analgesia is not exclusively regulated by the opioid system, as specific opiate antagonists can only reverse electroacupuncture-induced analgesia at some, but not all, its stages [2]. The identity of the neurotransmitter involved may be partially related to the frequency of electro-stimulation, but the precise mechanisms involved are unknown. Among the most important neurotransmitters potentiating the effect of electroacupuncture analgesia are serotonin and acetylcholine [5].

A major factor that might be associated with the endocrine aspects of acupuncture is stress-induced analgesia. Electroacupuncture is a stimulus that could be considered unpleasant, and thus act as a stressor. Needles are inserted and an electrical potential may be applied, usually in a strange environment. Pro-opiomelanocortin-derived peptides (ACTH and ß-endorphin) are released during stress and these are known to produce analgesia. The hypothesis that acupuncture leads to stress-induced analgesia has been raised and plasma cortisol, which is known to increase in response to a stressor, was elevated in man and horses [8] submitted to acupuncture.

Luna & Taylor (1998) aimed to study the potential role of endogenous opioids in mediating some effects of acupuncture by measuring central (cerebrospinal fluid), pituitary (pituitary venous effluent) and peripheral opioid concentrations in response to acupuncture, including evaluation of the relationship and relative contribution of each of these sources. Secondly, was to investigate whether acupuncture *per se* caused any stress response that would suggest its effect dependent on stress-induced analgesia, as suggested by previous studies in horses [8]. Few changes were observed for ß-endorphin and dynorphin, but peripheral plasma met-enkephalin concentration

increased 100% after 50 minutes, which suggests that acupuncture caused met-enkephalin release from peripheral sources only, showing that this opioid appears to be one of the most important for electroacupuncture-induced analgesia. CSF, peripheral and pituitary ACTH, catecholamines and cortisol concentrations were not modified by electroacupuncture, suggesting that electroacupuncture is not stress-induced analgesia and does not cause any endocrine response which could be related to stress.

Acupuncture may be used to potentiate anaesthesia or to treat acute or chronic pain. Eletroacupuncture was susccesfully used to perform caesarean section in bitches. Besides that, neonate dogs born from bitches submitted to caesarean section under inhalation anaesthesia showed a greater neurological and cardiorrespiratory depression when compared to bitches undergoing EA (eletroacupunture) [9]. A more common procedure is the use of acupuncture to potentiate both intravenous [10,11] and inhalation anaesthesia. Injection of microdosis of anaesthetics in acupoints [10,11] reduced the amount of anaesthetics to produce anaesthesia and also produced sedation in horses as well as the conventional dose of sedatives [12].

A study was performed to investigate the analgesic, cardiorespiratory, behavioral and endocrine effects of electrical stimulation of acupoints (unilateral and bilateral), comparing with false points and a control group [13]. Dogs were submitted to four different treatments: Gfalse (n=8): electrostimulation of false points; Gacep (n=8): no stimulation; G-EA/bil (n=8): EA in stomach 36 (St 36), gall bladder 34 (GB 34) and spleen 6 (Sp 6), bilaterally; G-EA/uni (n=8): as G-EA/bil but unilaterally. An alternate square wave dense disperse (10-1000 Hz) electrical stimulus was applied after sedation of all animals with 0.05 mg/kg of acepromazine IV. Analgesia was investigated by the response to thermical and mechanical stimuli applied at the thorax and abdmonen. The thermical stimulus was also applied to the interdigital space of the anterior limbs, measuring the time in seconds until reaction. There were no important cardiorespiratory differences either in time in each group or among the groups. The cutaneous pain threshold was higher after bilateral and unilateral EA compared to false points, however the latency period was shorter and analgesia was more intense and longer in the first group. Seventy five percent of the animals treated with both uni and bilateral EA were calm during treatment and 62,5% of the animals treated with false points showed signs of restlessness. Time to response to interdigital thermic stimulation was longer in bilateral EA group compared to the other groups. There was no difference in plasma cortisol concentrations. Bilateral electrical stimulation of St 36, GB 34 and Sp 6 acupoints produced a shorter latency period, a greater intensity and longer duration of analgesia, than unilateral stimulation. EA did not produce stress response as there were no cardiorespiratory and cortisol changes during treatments. Electrical stimulation of false points did not produce any effect, suggesting that it is necessary to stimulate proper acupoints to induce analgesia in dogs.

A great interest has recently been paid to investigate the effect of acupuncture on postoperative analgesia, compared to conventional analgesic therapy using opioids or antiinflammatory drugs [14]. Although the use of carprofen required less postoperative analgesic intervention, when compared to acupuncture and morphine, acupuncture was as effective as morphine, showing that dry needle acupuncture would have a promising effect to be used clinically to treat postoperative pain in dogs [14]. In another study, acupuncture was compared to meloxicam for perioperative analgesia in dogs undergoing elective ovariohysterectomy. There were no differences in pain score for 24 hs after surgery, and both were equally effective for postoperative analgesia [15]. According to the two studies mentioned previously, replacement of analgesic drugs in pre-anaesthetic medication prior to painful procedures is a potential and attractive use of acupuncture, to eliminate the side effects of conventional analgesics and reduce treatment costs. Dry needle acupuncture appears do be as effective as AINES and opioid analgesics, however maintenance of needles prior do anaesthesia might be cumbersome. Other advantages include the reduction in nausea, vomiting, analgesic requirement and metabolic and sympathoadrenal responses to surgery and improvement of blood coagulation, tissue healing and post-operative outcome.

Acupuncture has also been benefitial to treat neurological and musculoskeletal related problems,

most of them involving pain [16,17]. A good outcome was observed in above 60% of patients and is important to consider that most of these patients were referred as lost cases by conventional medicine. Electroacupuncture was more effective for recovering ambulation and improving neurologic deficit grade than decompressive surgery in dogs with longstanding severe deficits of thoracolumbar intervertebral disk disease [18]. The therapeutic approach in these cases, however, is based on Tradicional Chinese Medicine, an may be achieved by using points along the region of the meridian affected, influential and master points of certain areas, association points and points which produce general analgesia.

Acupuncture is a millenary Chinese technique with analgesic properties for acute, chronic, somatic and visceral pain well known all over the world. Neuro-humoral and neuro-endocrine mechanisms are involved in the effect of acupuncture: it modifies pain transmission and enhances pain endogenous inhibition by endogenous opioid peptides release [1]; as well as can attenuate inflammatory cascade [2].
Acupuncture may be used to substitute or supplement the use of conventional analgesic treatment for surgical pain both in healthy or sick patients, as conventional drugs, like NSAIDs or opioids, may present side effects or contraindications in some cases, especially when administered at high dosages, for prolonged time or in sick patients.
Morphine, Carprofen or Meloxicam are widely used for pre-emptive analgesia in dogs, as they are effective and relatively safe [3]. Although safety is one of the major advantages of opioids for pain management, possible side effects after their administration in man and animals may be observed, such as respiratory depression, urinary retention, excitement/dysphoria and histamine release. NSAIDs are commonly administered due to their analgesic and anti-inflammatory effects; however side effects may also be observed, especially gastrointestinal toxicity [4], hepatic and renal dysfunctions and coagulation disorders, mainly in patients with a previous history of these events.
Acupuncture was compared to Meloxicam for pre-emptive analgesia in bitches submitted to elective ovariohysterectomy. One group of patients was treated with Meloxicam and the other group was treated with acupuncture at ST36, GB34, SP6, LIV3, GB39 acupoints. Pain scores, obtained by behavioural and physiological responses based on an algometric scale after 1, 2, 6 and 24 hours after surgery, failed to reveal statistical differences between treatments, showing that acupuncture was as effective as Meloxicam [5].
Pharmacopuncture is the injection of sub-clinical doses of drugs into acupoints. This method combines the traditional acupoint stimulation with the local delivery of a pharmacological agent and it is supposed to potentiate and prolong the drug effects. Pharmacopuncture effectiveness was already demonstrate in other trials: sedation degree with systemic Acepromazine 0.1 mg/kg was the same of that produced with 1/10 of this dosage injected in GV1 in horse [6]; Xylazine 0.2 mg/kg injected into Yin Tang acupoint caused the same sedative effects of 1 mg/kg SC in dog [7].
A preliminary study was performed to compare postoperative analgesia produced by pre-emptive conventional doses of Carprofen, Morphine, acupuncture or pharmacopuncture with Carprofen or Morphine, administered before elective ovariohysterectomy in dogs. Post-operative pain measurements were recorded until 24 hours after recovery from anaesthesia, by a "blind" observer using four different internationally recognized pain scales (DIVAS – dynamic interactive visual analogue scale; UMPS – University of Melbourne pain scale; CSU – Colorado State University pain scale and SF-CPS- Short Form of Glasgow composite pain scale). Morphine rescue analgesia was administered when pain score was > nine points (above 33% the maximum score) according to UMPS score. No statistical differences were observed between groups when the number of rescue analgesia administered was considered. All treatments produced comparable degree of post-operative analgesia for 24 hours.

According to these results the use of either acupuncture or pharmacopuncture was equally effective as either Morphine or Carprofen to control postoperative pain in bitches submitted do OSH. Pharmacopunture appears to be as effective as acupuncture for postoperative analgesia in dogs submitted do ovariohysterectomy, and both were equally effective than opioid or NSAID pain treatment. The advantage of pharmacopunture when compared to the use of the conventional doses of drugs is the less side effects as well as cost reduction. The advantage of pharmacopunture when compared to dry needle acupuncture is that the injections may be performed quickly without maintaining needles before surgery.

Abstract
The aim of this work is to evaluate the analgesic effect of four electro-stimulated acupoints during TPLO (tibial plateau leveling osteotomy) in dogs. Twelve dogs were divided in two groups: group A (acupuncture) and group C (control). The same anesthetic and surgical management was used for each group. In the acupuncture group, disposable sterile needles, 0.25 x 13 mm, were inserted into the bilateral points 24 Bladder and 25 Bladder and, only contra-laterally as to the operated limb, into the 9 Spleen and 34 Bilious Bladder. Electroacupuncture stimulation started 20 minutes before surgery and finished at the end of surgical procedure. Cardiac and respiratory rates, end tidal CO_2 ($EtCO_2$), partial oxygen saturation (SpO_2), isoflurane concentration necessary to maintain a surgical plain of anaesthesia and analgesic supplementary treatment required during surgery (fentanyl iv in bolus) were recorded and plasmatic cortisol level was measured before, after 40 minutes from the beginning and at the end of electroacupuncture stimulation. Statistical analysis was performed using *t*-student test and ANOVA. No differences were recorded between groups about cardiac and respiratory rates, $EtCO_2$ and SpO_2. Mean isoflurane concentration and fentanyl required were significantly lower in the acupuncture group than in the control one. After 40 minutes the plasmatic cortisol was significantly lower in the acupuncture group. No difference was recorded in plasmatic cortisol between groups at the end of electroacupuncture stimulation. This work points out that electroacupuncture stimulation of these 4 acupuncture points is useful to increase analgesia during TPLO in dog.

Introduction
Acupuncture is the application of small-gauge needles to various points on the body for the purpose of eliciting physiological responses in the treatment of almost any disease, especially for relieving pain. A primitive acupuncture-like therapy was practiced in India some 7000 years ago, but it has been mentioned for the first time in the book "Historic memories" by MaQian in the 2nd century b.C. One of the earliest records of veterinary acupuncture was some 3000 years ago in India for the treatment of elephants. The professional figure of veterinary surgeon has been appeared during Zhong dynasty 1027-221 b.C.) and veterinary acupuncture became a separated branch of the traditional Chinese medicine, but the father of veterinary acupuncture is generally considered to be Shun Yang (480 b.C.) from China (Schoen 2001).
Clinical studies, on both humans and dogs, point out that acupuncture is beneficial in cases where analgesics and anti-inflammatory medications had been ineffective. Acupuncture was employed in dogs, cats, horses and cattle (Sánchez-Araujo et Puchi 1997, Schoen 2001, Cassu et al. 2007, Muir et al. 2007, Lin et al. 2008). It plays an important role in racing horse to treat muscular and skeletal diseases and reproductive and intestinal pathologies because there are no problems with anti-doping test (Merritt et al. 2002).
Even if acupuncture has been performed for thousands of years, it was employed recently as an anaesthetic technique. A tonsillectomy was performed, for the first time, with only this anesthetic management in 1958 (Lee et Ernst 2005). In veterinary medicine, it is difficult to use only acupuncture as anaesthetic regimen because electro-stimulation itself is painful and the animals do not stand still. Wallis et al. (1974) showed that acupuncture analgesia is not adequate by itself for surgery. Then, many studies point out that acupuncture is useful to reduce surgical pain (Lee et

Ernst 2005, Muir et al. 2007). Tseng et al. (2008) have demonstrated that electro-acupuncture produce analgesia and is able to reduce halothane minimum alveolar concentration (MAC).
The aim of this work is to evaluate the analgesic effect of four electro-stimulated acupoints during TPLO (tibial plateau leveling osteotomy) in dogs.

Materials and Methods

Twelve dogs referred to the Department of Animal Health of the Faculty of Veterinary Medicine of Parma with the rupture of cranial cruciate ligament were considered. The dogs were treated with TPLO (tibial plateau leveling osteotomy). The features of the patients were reported in table 1.

Table 1: Breed, age, weight and sex (M: male; F: female) of the dogs of the study.

1	**Breed**	**Age (months)**	**Weight (kg)**	**Sex**
	American Staffordshire Terrier	60	27	M
2	American Staffordshire Terrier	24	31	M
3	American Staffordshire Terrier	30	19	F
4	Boxer	84	37	M
5	Pointer	60	28.9	M
6	Dobermann	72	40	M
7	Dogue de Bordeaux	60	50	F
8	Dogue de Bordeaux	72	60	M
9	Labrador Retriever	96	32	F
10	Labrador Retriever	84	39.5	F
11	Corso	24	56.5	M
12	Corso	72	47	M

The dogs were divided in two groups: group A (acupuncture) and group C (control). The same anesthetic and surgical management was used for each group. In the acupuncture group, disposable sterile needles, 0.25 x 13 mm, were inserted into the bilateral points 24 Bladder and 25 Bladder (figures 1 and 2) and, only contra-laterally at the operated limb, into the 9 Spleen (figure 3) and 34 Bilious Bladder (figure 4).
Electro-acupuncture treatment instrument SDZ III (Hwato) was employed because of its ability to work at different frequencies to give pulsation with different frequencies for a constant activation of acupoints. The frequency of every wave was 100 Hz while intensity was progressively increased until reaching muscular contractions. The anesthetized dogs were treated by electro-acupuncture stimulation from 20 minutes before surgery to the end of surgical procedure.

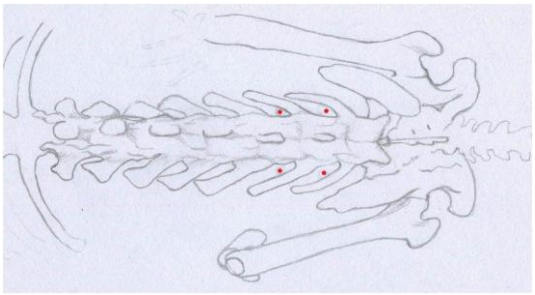

Figure 1: red spots show dorsoventral localization of acupoints 24 Bladder and 25 Bladder

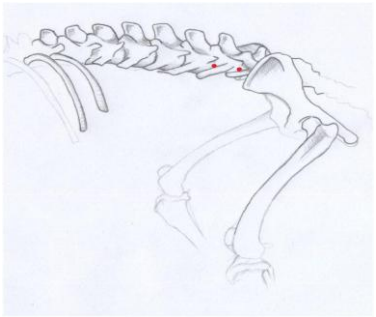

Figure 2: red spots show laterolateral localization of acupoints 24 Bladder and 25 Bladder

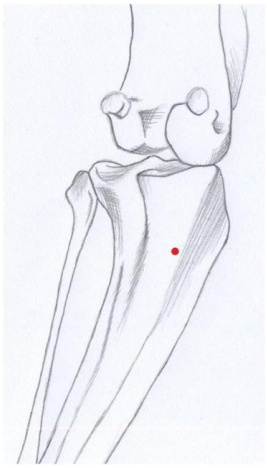

Figure 3: red spot shows acupoint 9 Spleen

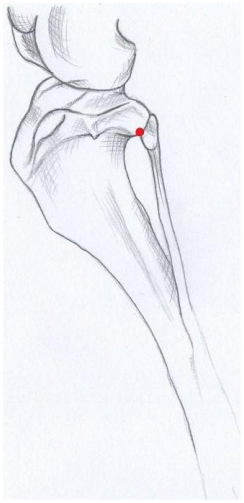

Figure 4: red spot shows acupoint 34 Bilious Bladder

The same anesthetic regimen was used for all dogs: premedication was made by a mixture of medetomidine 10 μg kg^{-1} (Domitor or Sedator®) and butorphanol 0.2 mg kg^{-1} (Dolorex or Nargesic®) im and after 20 minutes a venous catheter was placed in the cephalic vein and a fluid therapy with Ringer lactate solution 5-10 ml kg^{-1} h^{-1}. Carprophen 4 mg kg^{-1} (Rimadyl®) and cephazoline 20 mg kg^{-1} (Cefazolina Dorom®) were administered iv before anesthesia induction with propofol 2-3 mg kg^{-1} (Rapinovet®) iv; an orotracheal tube of Ruesch was placed and anesthesia was maintained by isoflurane (Isoflo®) in oxygen. If necessary, fentanyl 2-4 μg kg^{-1} (Fentanest®) iv was administered to ensure intraoperatory analgesia; buprenorphine 10 μg kg^{-1} (Temgesic®) iv was administered 30 minutes before the end of surgery.

Cardiac and respiratory rates, end tidal CO_2 ($EtCO_2$), partial oxygen saturation (SpO_2), isoflurane concentration necessary to maintain a surgical plain of anesthesia and analgesic supplementary treatment required during surgery (fentanyl iv in bolus) were recorded. Cardiac and respiratory data were obtained using the monitors Guardian (Schiller) and Capnomac II (Datex). Cardiac and respiratory rates, $EtCO_2$ and SpO_2 were recorded at five times: T0 (before surgery), T1 (skin incision), T2 (tibial periosteum incision and retraction), T3 (tibial osteotomy) and T4 (skin suture). Plasmatic cortisol level was measured to quantify the effect of electro-acupuncture treatment. The blood samples were collected before (pre), after 40 minutes from the beginning (intra) and after the end (post) of electro-acupuncture stimulation. Plasmatic cortisol level was tasted by the kit Demetic Cortisol ELISA. The samples were refrigerated and stored and the plasmatic cortisol determinations were made at the same time.

T-student test was employed to analyze the following data of the groups: age, weight, cardiac and

respiratory rates, $EtCO_2$, SpO_2, isoflurane concentration and dose of fentanyl. Statistical analysis of plasmatic cortisol level was performed using a ONE-way ANOVA analysis of the variance.

Results

Two dogs were stormed from the study, one for each group: the former because the veterinary anesthetist was not the same and the latter because it showed plasmatic cortisol level before electro-stimulation higher (pre 383.1 ng ml^{-1}) than normal physiological values.

The mean age of the ten dogs was 39.9 ± 96 months and mean weight 59.4 ± 14.03 kg. There is no significant differences between groups about age and weight even if the subjects of acupuncture group are younger than the others: group A 34.7 ± 20.33 months and 42 ± 12-05 while group C 76.8 ± 13.68 months and 45.2 ± 11.03 kg.

Cardiac rate ranged between 75.6 ± 12.81 (T0) and 86.4 ± 15.15 (T2) bpm (beats per minute) in acupuncture group and between 56.4 ± 19.41 (T0) and 92.25 ± 12.29 (T2) bpm in control group. There were no significant differences between groups, but in control group cardiac rate was significantly higher at T2 than T0.

Respiratory rate ranged between 10 ± 4.79 (T4) and 16.8 ± 6.90 (T2) apm (acts per minute) in acupuncture group and between 10.4 ± 4.56 (T0) and 14.8 ± 4.60 (T2) bpm in control group. There are no significant differences between groups and inside of the groups.

No significant differences were recorded about $EtCO_2$ and SpO_2. They always showed physiological values: $EtCO_2$ ranged between 35 and 45 mmHg and SpO_2 between 95 and 99%.

Isoflurane concentration was 1.77 ± 0.18% in group A and 1.90 ± 1.16% in group C: there is no significant difference between groups even if the concentration in group C are higher than in group A.

The mean dose of fentanyl was 1.43 ± 2.79 μg kg^{-1} in group A and 2.1 ± 1.82 μg kg^{-1} in group C: there is no significant difference between groups even if the percentage in group C are higher than in group A.

The plasmatic cortisol levels of the dogs of group A were 16.14 ± 16.23 ng ml^{-1} (pre), 16.83 ± 29.30 ng ml^{-1} (intra) and 61.38 ± 39.45 ng ml^{-1} (post). The plasmatic cortisol levels of the dogs of group C were 16.88 ± 11.33 ng ml^{-1} (pre), 35.14 ± 44.02 ng ml^{-1} (intra) and 69.35 ± 36.24 ng ml^{-1} (post). The difference between intra and pre values is significant in group C while the plasmatic cortisol level intra was significantly higher in group C than in group A.

Discussion

Electro-acupuncture has been studied for relief of experimentally-induced pain in animals and many studies pointed out that electro-acupuncture analgesia is adequate in mice and rabbits (Tseng). According to Stoelting et al. (1973) there are no changes in halothane MAC in the dogs treated with electro-acupuncture. On the contrary, Tseng et al. (1981) demonstrated that electro-acupuncture produced a statistically significant decrease in halothane MAC in dogs. Our data show a significant decrease in isoflurane concentration in dogs treated with acupuncture suggesting that electro-acupuncture might be a useful adjuvant analgesic method. Besides, in contrast with a previous work (Lee 1975), this study highlights that electro-acupuncture has no effect on cardiorespiratory system. Analgesic effect produced by electro-acupuncture is supported also by plasmatic level of cortisol. It is known that plasmatic level of cortisol increases during surgery in dogs and cats (Bianchi et al. 2001). Our results show that electro-acupuncture reduced plasmatic level of cortisol in dogs suggesting that electro-acupuncture improves analgesia during surgery. Unfortunately the plasmatic level of cortisol is the same in both groups, with or without acupuncture, at the end of electro-stimulation: probably beneficial analgesic effect does not last over time.

However, our results encourage the use of electro-acupuncture to improve intraoperative analgesia

Acknowledgments

FIBROMYALGIA: HOW TO TREAT IT BY ACUPUNCTURE.

Nicola Brizio

Acupuncture and Auriculopuncture Unit
P.S.I "S. Maria di Loreto Crispi" ASL NA1

Fibromyalgia is a common type of musculoskeletal pain characterized by both wide diffusion and fatigue.
It is by far one of the most diffused rheumatic diseases: it can be deemed that in Italy only between 2 and 4 million individuals are affected, and most of them are women.
The term Fibromyalgia or fibromyalgic syndrome means: pain in the muscles and in the fibrous connective tissues. Fibromyalgia is actually a type of extra-articular or flesh rheumatism and, although it is similar to an articular pathology, it is not "arthritis" and it does not cause any deformity of articular structures.
It can be often confused with other kinds of pathologies, because some of its associated symptoms can be found within other clinical conditions.
These studies have shown that some symptoms, like the diffused musculoskeletal pain, together with the presence of specific areas resulting algogenic when finger pressed, the so-called "Tender Points", can be found within those patients affected by fibromyalgic syndrome and not in healthy people or patients suffering from other painful rheumatic pathologies.
The fibromyalgic syndrome does not have any alterations that can be detected by lab analyses nor causes any damage detectable by X-rays. In effect the diagnosis is mainly due to those symptoms referred directly by the patient.
Being fibromyalgia a cronical disease that tends to get worse slowly in time, it frequently occurs that a patient suffering from it can react to it by getting anxious and depressed.
Pain is fibromyalgia predominant symptom. Generally, it appears within the whole body, even though its starting point can be delimited to a specific area, like the cervical rachis and the shoulders, and from there it can subsequently diffuse to other areas.
Such a pain is described according to a great variety of ways: burning sensation, rigidity, contracture, tension, etc. . FM is a disease affecting the muscles in such a way to cause a muscular tension increase: all muscles undergo a constant tension and hurt.
The hypertonic muscles do not allow the patient to rest properly: the person affected by FM is a light sleeper who often wakes up during the night and who feels more tired than the night before, when he finally wakes up in the following morning.
The muscular tension is reflected in the tendons thus causing pain particularly at their insertion points: these painful points, together with some muscular points which can be detected during a medical examination by simply touching, represent a characteristic peculiar to FM.
FM disease origin is due to a multifactor perspective. The real cause of such a syndrome is still unknown at present. A lot of various factors can induce a fibromyalgic syndrome. For example some stressing events can lead to the disease typical symptoms. It is highly unlikely that the fibromyalgic syndrome can be induced by a single cause.
Several studies have been carried out in order to investigate the disease causes and they have documented various alterations of the neurotransmitters at the level of central nervous system, that is to say those substances that are of the maximum importance within the communication among nerve cells.

Actually the fibromyalgic syndrome would seem depending on a reduced pain threshold due to an alteration of perception modalities relevant to somaesthetic inputs by the central nervous system (nociceptive threshold alteration).
FM can be then considered essentially a pathology relevant to intercellular communication.

The two characteristics present are **hyperalgia** and **allodynia**.
One of the effects of the neurotransmitters dysfunction, and particularly of serotonin and noradrenaline, is Neurovegetative Nervous System hyperactivity that causes a vascularization deficiency at muscular level with subsequent pain, asthenia and tension appearance.
In addition to the two main symptoms, pain and tiredness, a lot of other clinical signs can be present within FM outline and the association of such symptoms can partly explain the difficulties encountered as far as FM diagnosis is concerned.

Asthenia and sleeping disorder
Headache or face pain
Tinnitus
Esthesia disorder
Gastrointestinal disorder
Urinary disorder
Dysmennorhea
Temperature alterations
Rigidity
Tachycardia
Cognitive disorder
Allergies

Pathogenesis is still the most controversial matter
One of FM characteristics is the sympathetic hyperactivity that turns particularly into alterations of peripheral and central microcirculation.
Alterations of several neurotransmitters have been shown within FM disease, as a proof of FM "central" origin: reduced concentration of serotonin and 5-Hidroxy-tryptophan in liquor and plasm, melatonin reduced production, an over three-time increase of P substance concentration in the liquor. All these neurotransmitters are involved in the pain modulation and sleep regulation.
The response to the relaxation therapy and to selective serotonin reuptake inhibitors (SSRI) allows to think that the predominant deficiency within FM is the one associated to serotonin syndrome.
We can basically distinguish two categories of medications used to treat FM: the myorelaxing ones, that act on FM "peripheral" appearance, that is to say on the muscular contracture, and those intended to potentiate serotonin activity which act instead on one of the disease "central" mechanisms.
Generally these medications are combined within the same patient.

- **SSRI**
- **SNRI**

The sympathetic and parasympathetic systems can be compared to TCM Yin/Yang dualism: the first one prepares the body to face stress or emergency situations, while the second one provides for the functions associated to digestion and sleep.
The sympathetic main neurotransmitter is adrenalin, while acetylcholine is the one concerned within the parasympathetic one.
The most correct therapeutic approach for FM should foresee a Sympathetic tone reduction, then a Yang lowering by Yin stimulation in the initial phases; afterwards, in case the sympathetic hyperactivity status goes on in time thus leading to a Yang lack (emptiness), Qi stimulation becomes necessary.
The National Institute of Health (NIH), on the basis of reviews released within literature from 1970 to 1997, in the National Health Development Panel on Acupuncture has stated Acupuncture utility within Fibromyalgic Syndrome therapy, and this both as an additional treatment and as an acceptable alternative to conventional methods.
Acupuncture is associated both to a pain reduction and to an increase of pain threshold and, in addition, the variation of neuropeptides levels that matches the acupuncture treatment, like serotonin ( ) and P substance ( ), has been documented.

Acupuncture interferes in neuroendocrine physiology at several levels:

- It acts on the hypothalamic-pituitary-adrenal axis (HPA axis);
- It adjusts release of opioid peptides as well as other neuropeptides like orphanin, P substance, CCK, angiotensin II, VIP, only to mention some of them;
- It modifies GnRH release by means of the endorphins.

According to TCM, that is by definition global and unitary medicine, only the patient exists while disease doesn't and, as a consequence, a separation between physical and psychic symptoms can only be unconceivable, even only from a theoretical point of view.
For this reason, according to the classical TCM principles, the FM equivalent, as intended by western medicine, does not exist, therefore a standard therapy neither can nor must exist.
In the initial stage (I stage) a condition of a lack (absence, emptiness) of Spleen Qi associated to and made worse (more serious) by a stagnation of Hepar Qi is observed; when these energetic alterations go on in time an emptiness of Blood is obtained with a penetration into the meridians by Cold (II stage). If a correct therapy is not started, the disease gets worse because of the consumption of all vital substances, mainly kidney Yang and Jing. (III stage).
A precise relationship between muscular tissues and extraordinary meridians exists. The Dai Mai/Yang Wei Mai couple takes care of the transverse growth and it is connected to upper and lower limbs maturation. Use of these two "curious" Dai Mai and Yang Wei Mai key points in pair is highly active in the wandering myoarticular pains, mainly when associated to a strong psychic engagement.
By observing the psycho-physical characteristics of fibromyalgic patients and by taking into account the symbolic meaning of tendon-muscular secondary meridians as well as of extraordinary Dai Mai and Yang Wei Mai meridians, we have treated 15 patients affected by FM by means of simple acupuncture on Zulinqi (GB41) and Waiguan (YB5) points with a bilateral approach, in addition to those points peculiar to muscles under hypertonia and those connected to the energetic diagnosis, and we have also treated other 15 patients with false acupuncture who were at the same time under pharmacological treatment.
12 twice-weekly somatic acupuncture and auriculo-puncture sessions, each one lasting 30 minutes have been carried out:
GB 41, it is Dai Mai opening point and it starts its energetic sequence; specific point for head affections; it treats occipital algia (pain); it dissolves Humidity-Heat, it helps Hepar Qi to flow freely, it treats coxalgia when combined with SP6.
TB 5, it is Yang Wei Mai opening point; it is one of the main points to free the outside (used to treat Tai Yang level) to discharge Wind-Heat. It is the most important point to treat Shao Yang when pathogen energy is half inside and half outside (alternation of chilly sensation and fever, symptoms originating from Qi stagnation) it is good for the ears; it subjugates Hepar Yang (temporal migraines)
CV12, ST36, SP3, SP6, BL20, BL21, GB34, LR3, LR13, LR14, TB6, PC6, HT7, CV14, CV15, CV4, CV6 are some of the points used according to the criteria of disease stage and energetic diagnosis.
Shen Men points, 0 point and occiput in a bilateral way, and sensitive points have been used for each patient after auricle examination.
A reduction of muscular rigidity and of spontaneous pain, in addition to the induced one was observed after 4 weeks in 10 of the patients treated within the first group as well as an improvement of psychic symptoms in the remaining 5 patients, while the symptoms variation within the second group of patients under pharmacological treatment was modest (poor).
A reduction of muscular rigidity and pain as well as a mood improvement was observed after 4 weeks more in 8 patients of the second group.
Within the second group, after the first 4 weeks, we reduced pharmacological dosage and we replaced false acupuncture with real one.
Such an acupuncture treatment has shown various parameters improvement like myalgic index,

number of sensitive tender points, with a consequent improvement of life quality. This has allowed a reduction of allopathic medications use.
Although FM pathogenic etiology and mechanisms continue to be almost unknown, it seems evident that the same pathogenic mechanism is responsible for the psychic and physical disease symptoms. At present we know that central nervous system functions are adjusted by chemical messengers that include neurotransmitters and neuropeptides and that the release of these substances can be modulated by acupuncture.
The purpose of such a study, which will last for a long time in the future, will focus not only on confirming acupuncture therapeutic effectiveness and absence of collateral effects, but also and mainly on demonstrating how it will be possible to prevent relapse phases and disease progress for the single patients and on the basis of their individual weakness.
This will be accomplished by means of a close follow up which will foresee, in addition to acupuncture, also medical physical exercise, dietetics and phytotherapy, and, possibly, association with allopathic medications.

PAIN THERAPY BY ACUPUNCTURE IN SPORT HORSES

Pain and suffering have a negative impact on the horse's performance and quality of life.
Traditional Chinese Veterinary Medicine (TCVM) provides a number of clinical methods for treating pain.
One of the most crucial parts of pain therapy consists of recognizing the changes in character and attitudes that denote pain: licking, biting, scratching or shaking the affected area, changes in the skin and coat, alterations in the posture and gait, excessive perspiration, and even more intensive symptoms such as changes in the appetite or intestinal peristalsis[ ].
In hippiatrics, there is a consolidated system of diagnostic acupoints, which makes it possible to identify the organs involved in the disorder or the seat of limb diseases, and is thus particularly useful in sports medicine. According to E.C.I.W.O. (Embryo Containing the Information of the Whole Organism) theory, the Ting points, which are among the Antique Shu points, the Bei Shu points, the Mu points and the points on the ear form diagnostics systems that are linked to the complex network of relationships between the internal organs and external areas, and can be investigated by palpation.
Through this direct contact, we can evaluate and quantify the patient's energy, and in this way interact with the patient through wave functions that create an information flow[ ].
In dealing with the disease, it is essential to formulate a correct 'energy diagnosis' which establishes the state criteria, or in other words the general situation affecting the animal's organism, conditions of excess or deficiency expressed through physical and functional signs[ ].
Treatment acupoints are selected on the basis of the traditional indications regarding their energy, as well as experimental evidence.
Their action manifests itself at different levels: antalgic, anti-inflammatory, neuroendocrine, trophic and vasomodulator activity in an integrated system that elicits specific functional responses.
There are different ways of stimulating the acupoints: with Chinese needle: hydro-acupuncture, electroacupuncture, laserpuncture[ ].
The diseases that can be treated fall into eight categories:

- Recurrent lameness
- Osteoarthritis
- Navicular disease
- Acute and chronic dorsal pain
- Endocrine syndrome
- Postoperative pain
- Myofascial pain
- Visceral pain.

The authors have assessed the effectiveness of each way of stimulating the acupoints for each of these clinical conditions.

Recurrent lameness: This is a common problem in horses, in which a specific joint segment which has been subject to a prior phlogistic process is periodically affected by inflammation to a greater or lesser extent, so that there is a relapse of lameness. Allopathic medicine treats each relapse with a local infiltration.

Keidel (1999) notes that acupuncture modifies the engrams, i.e., the patterns of cooperation between nerve bundles at the level of the CNS, thus promoting its ability to heal persistent disorders[ ].

In these disorders, the best results are achieved by applying traditional acupuncture and using points such as Neiguan and Houxi which are used specifically to treat chronic and recurrent diseases, and can bring about a change in the engrams which helps the area concerned return to a normal structural and functional condition.

Osteoarthritis: Especially common in elderly patients, these chronic diseases are characterized by periodic relapses accompanied by pain and limitation of movement.

In these diseases, the best results are achieved by applying traditional acupunture to modify bone metabolism, specifically with acupoints such as Dazhu and Huantiao; local application of acuelectrostimulation is highly effective[ ].

Navicular disease: This is a complex syndrome that starts as a podotrochlear bursitis, i.e., as an inflammation of the bursa between the deep digital flexor tendon and the navicular bone. As the inflammation progresses, it causes degenerative and erosive lesions of the fibrocartilage, which ulcerates at the sagittal ridge. The fibrils of the tendon tear at the distal edge of the navicular bone.

The early stages of the disease can be treated with traditional acupuncture and with acuelectrostimulation, chiefly using the Qian Ti Men and Ming Tang acupoints. In more advanced forms of the disease, the best treatment is laserpuncture, which induces significant anti-inflammatory and analgesic effects; above all, it promotes tissue growth and increases circulation in disorders accompanied by vessel occlusion, where it boosts capillary circulation and microcirculation[ ].

Laser stimulation has been found to have an important effect in treating these diseases: in addition to pain relief, the results thus obtained show a marked drop (±50%) in levels of endogenous cortisol, confirming the lower state of stress produced in all patients[ ].

Acute and chronic dorsal pain: Biomechanically, the vertebral column is crucial for all of the horse's movements. From the physiological standpoint, the column must follow a series of curves which allow the limbs to function correctly, balance to be maintained, and all of the necessary shifts in the animal's center of gravity to take place. In TCVM, the vertebral column is in the path of the Du Mai curious meridian. Specific acupoints are used according to the region involved.

Cervical region: Vertebral subluxations can occur which cause disorders in the biomechanical or neurological functions (a particular form of cervical ataxia resulting from traumatic injuries, osteochondritis dissecans or congenital lesions of this region is Wobbler Syndrome). Treatment is based on the use of the traditional Jiu Wei point (in reality, this is a group of nine points that form an arc on the lateral aspect of both sides of the neck).

Thoracic region: This region of the column should be regarded as an integral part of the thoracic cavity; it must permit flexion, extension, lateroflexion, rotation and translation, all movements that are limited by the structure and the function of the sternum and diaphragm. Here as in the cervical region, vertebral subluxations can occur which reduce the range of movement. Treatment is based on the use of the corresponding acupoints of the Du Mai, the Bladder channel and, above all, the Hwato Jiaji system of paravertebral points

Lumbar region: This entire section of the vertebral column is to be considered as the source of movement for the whole animal. Among other movements, it produces two fundamental flexion and extension movements that can be compared to the stages of loading and unloading a spring. The most common disorder of this region is the Chronic Lumbar Pain Syndrome.

According to TCVM, this is a typical Bi-Syndrome caused by blocked Qi (energy) and Xue (blood) circulation. Initially, this stagnation affects only the muscular component, and more specifically involves the dorsal longissimus and the lumbodorsal fascia. When the contraction of these muscles persists, the fascia lata tensor is involved, causing an alteration in movement. In addition, continuing contraction generates a misalignment of the vertebral bodies, which has profound effects on gait. When mares present with pain at this level, it is important to perform differential diagnosis with the Endocrine Syndrome. Traditional treatment consists of using moxa (placed in a wooden box), and the Wei Zhong, Wu Shu, Yang Ling Quan, Ming Men and Guan Yuan acupoints.
Sacral region: The sacrum, formed from the fusion of five vertebrae, is of particular importance in TCVM, as it is the dorsal wall of the Dan Tian (Lower Cinnabar Field), a species of chamber inside the pelvis which stores ancestral energies and contains the Jing Chamber (Uterus / Prostate). Its function is to permit oscillation of the ilium and forward transmission of movement towards L6; in addition, it must allow the coccygeal vertebrae to function as a rudder for the entire column. As it acts as a aileron, the sacrum can be subject to malpositioning, with immediate effects on the rocking motion of the pelvis that are extremely detrimental to gait. Treatment consists of using Zao Bai Hui and the Liao acupoints, a term that means hole and refers to the sacral foramina: Shang Liao, Ci Liao, Zhong Liao, Xia Liao. It is preferable to use traditional Chinese metal needles and apply a moxa stick for each, thus taking advantage of the relaxing and tonic effects of heat.
Coccygeal region: This sector is made up of 17 – 21 small vertebrae whose size decreases from the first to the last (only the first two are fully formed); the apparently random movements of the tail enable the entire column to be mobilized. The most frequent disorders in this area are the result of traumatic injuries that can limit movements, with major repercussions on all of the preceding regions. The acupoints for this region are shown on the most ancient Chinese table: Wei Gen, Wei Ben, Wei Jian[ ].
Endocrine syndrome: This is a particular syndrome that affects competition mares. The causes of the disease lie in the type of life led by these patients and in certain psycho-behavioral factors: stress from training, competitions, rigidly controlled diet, lack of reproductive activity and, in some cases, the use of performance-enhancing drugs. Lumbar pain radiates to the hindlimbs, the lumbosacral and coccygeal areas are extremely sensitive to palpation, and the mare presents rigid movements, pain and tension in the paralumbar fossa, particularly on the left. There is often an involvement of the neck and the associated local path of the Triple Burner channel. Treatment is based on the use of acupoints that both regularize the endocrine axis and act on the algic component: Shenshu, Jingmen, Mingmen, Yangchi, Huangmen, Jingming, Zhiyin. The Shenshu acupoint is highly effective, and can also be stimulated with hydro-acupuncture. Transrectal massage of the uterus is also beneficial: according to the classic Taoist text Su Nu Jing, this technique restores normal uterine functions, promotes production and maturation of the eggs, and aids the well-being of the entire female organism. Stretching and Tuina (Chinese massage) can also be applied to advantage[ ].
Postoperative pain and visceral pain: Where possible, treatment should be preventive, with the patient undergoing one or two sittings before the surgical procedure. In this way, a number of traditional acupuncture techniques can be used which have an antalgic effect and improve the trophism of the tissues involved in the operation. Where treatment is applied postoperatively, specific techniques are used to treat the surgical wound[ ] and to eliminate pain. These techniques chiefly employ local needling or electroacustimulation. In veterinary medicine, Kothbauer and Schwartz performed a thorough investigation of the Bei Shu points, finding that they behave as small areas that reflect somatic pain from the internal organs. This enables them to be used in diagnostics and treatment.
Myofascial pain: Pain is expressed in specific areas of the body that become particularly sensitive, to the point where they cause contractions in the muscle groups known as trigger points. Abnormalities of the internal organs can also cause limited contractions, stiffness and hardening of the muscles, as a means of protecting the affected organ. Cutaneous stimulation of these areas can

influence the condition of the internal organs through the medullary nerves, causing peristaltic movements, organ contractions, increased liver perfusion, hormone secretion and the consequent reduction or disappearance of the tension at the trigger points[ ].
Treatment involves special techniques for stimulating the affected areas with traditional acupuncture and hydro-acupuncture. The affected organ is also treated via its connections with the corresponding somatotype (usually one of the Bei Shu points).
According to these clinical experiences it is possible to infer that:

- electroacupuncture is more effective in treating acute conditions, it induces the pain disappearance quickly, but the antalgic effect has average length;
- hydro-acupuncture produces a good level of muscle relaxation and improve the metabolic capacities in competition horses: it is the best technique to increase the sport performance;
- traditional acupuncture (dry needles) promotes an analgesic level more slowly but more prolonged in length, besides it induces manifest effects on organic metabolism;
- laserpuncuture determines effects like the traditional acupuncture.

Independently from the technique employed, it is very significant that acupuncture has a relevant anti-stress effect: at the local antalgic and anti-inflammatory action corresponds a general effect on biological functions of the organism; the acupuncture assures the complete wellbeing of the horse and it acts on global energy of the body resulting "naturally" effective.

Introduction

Adequate assessment of pain using validated tools appropriate to the population or individual is an essential prerequisite of successful pain management [1]

Pain assessment is the first step in proper pain relief, but many factors compromise patients' ability to communicate verbally including the use of sedative agents, and mechanical ventilation [2].

Sources of pain in critically ill patients include the existing medical condition, traumatic injuries, surgical or medical procedures, invasive instrumentation, blood draws, and other routine care such as suctioning, turning, positioning, drain and catheter removal, and wound care. In addition, immobility, hidden infection, and early decubiti can cause pain and discomfort [3].

Verbal adult patients describe a constant baseline aching pain with intermittent procedure-related pain descriptors such as sharp, stinging, stabbing, shooting, and awful pain; thus it should be assumed that those unable to report pain also experience these sensations.

Pain evaluation by observational (Behavioral) scales is a great challenge. Different scales have been valitated, and each of them used facial expression, vocalization, and body movements as indicators of pain. It's difficult to adapt one scale for every kind of patients and further sudies are required to define the use of observational study of pain.

Behavioral Pain Assessment Tools

Behavioral tools have good psychometric properties. This instrument might prove useful to measure pain in uncommunicative critically ill patients and to evaluate the effectiveness of analgesic treatment and adapt it.

Although no single behavioral scale has been shown to be superior to others, clinicians should select a scale that is appropriate to the patient and types of pain on which it has been tested [4].

Behavioral pain assessment is not appropriate for pharmacologically paralyzed infants, children and adults, or those who are flaccid and cannot respond behaviorally to pain [5].

Use of these instruments in critical care practice is restricted because of the limitations of the studies.

Limitations include small sample sizes, lack of validation in intubated patients,use of a subjective scale (eg, absence, slight, moderate, and extreme intensity of behaviors),confusion in the definition of behaviors (eg, body movements and muscle rigidity), and use of dependent observations (ie, statistical analysis of the observations rather than of the sample of patients).

Clinical feasibility, or the ability to readily adapt an instrument for routine assessment and documentation, may depend on a tool's simplicity and its compatibility with other tools used in the clinical setting,as well as on the ability to use the tool across settings or populations of patients.

In elderly dementia and other damages to the central nervous system that affect memory, language, and higher order cognitive processing necessary to communicate the experience impact the ability to communicate pain to health care providers. [6].

FLACC Behavioral Scale

FLACC Behavioral Scale has excellent psychometric properties, including reliability, criterion validity, and construct validity, in assessing pain in these patients.

Interestingly, 4 categories (face, legs, activity, and consolability) were predictive of most of the variance in scores.

The cry category correlated poorly with other categories and slightly lowered the internal consistency of the tool.

These findings are not surprising, because many of the patients in this study were nonverbal and

many had endotracheal tubes. FLACC tool were meant to indicate some of the differences observed from patient to patient. However, assessment of chronic or long-term pain should include other observations such as activity, quality of sleep, and expres- sions of depression.

Variety of medical and surgical patients in the sample indicate usefulness of FLACC across critical care settings. FLACC scores are comparable to scores generated by using 0-to-10 number rating scales.

Patients having difficulties with verbal communication (mechanically ventilated or having been tracheally extubated less than four hours), showed that the most frequently noted physiological indicators of pain were increased heart rate and increased arterial blood pressure.

However, it is agreed that these physiological indicators lack specificity in the ICU and can be influenced by many medications (vasopressors, alpha-adrenergic blockers, antiarrhythmics, sedative drugs, etc.) and pathological conditions (sepsis states, shock, hypoxia, and fear) .

The facial scales and upper limb movements contributed to the pain rating more than compliance with mechanical ventilation. The reason could be that this subscale might be affected by some factors unrelated to pain, such as hypoxemia, bronchospasm, and mucous plugging, which can lead to coughing and some fighting of the ventilator.

Newer modes of ventilation more adaptable in patients' needs may reduce the reliability of this category in assessing discomfort.

Further studies are required to determine whether the use of this scale can really improve management of pain in the critical care setting [7].

CHEOPS (Children's Hospital of Eastern Ontario Pain Scale)

CHEOPS (Children's Hospital of Eastern Ontario Pain Scale) is a behavioural scale used to monitor the effectiveness of interventions for reducing pain and discomfort and valitated initially, in children aged 1–5 years, and subsequently validated in children from other populations and ages. Pain score is obtained from adding points from six different parameters range from 4 to 13.

Use of either the FLACC (Face, Legs, Activity, Cry, Consolability) or the CHEOPS (Children's Hospital of Eastern Ontario Pain Scale) is recommended for pain associated with medical procedures and other brief painful events. Both have been very extensively used and have excellent evidencem of reliability, validity, and responsiveness. The FLACC comprises five items scored 0–2 as identified in the name of the scale. It is lower in burden than the CHEOPS, and the 0–10 FLACC scores are more readily interpretable.

In any particular procedural pain context, the choice between the two instruments will depend on how important it is to use an instrument with low burden and a commonly understood metric (in which the FLACC has the advantage) or to avoid inferences about 'consolability' (in which the CHEOPS has the advantage). The FLACC is recommended as the first choice for post-operative pain in hospital, as it was designed and validated in this clinical context over a broader age range than the CHEOPS. Moreover, the variable of 'consolability,' or response to supportive contact and distraction, may be generally more feasible and important to assess in post-operative care (which lasts for a longer period of time) than it is in brief procedural pain.

The COMFORT scale

The COMFORT scale is recommended for pain in children in critical care as it is the only well-studied instrument that makes explicit accommodation for constraints placed on the behavioral expression of pain by mechanical ventilation and physical restraint. The inter-rater reliability and internal consistency of this scale are strong. It requires scoring 8 items from 1 to 5, for a total score from 8 to 40; it includes a requirement for comparison of blood pressure with baseline levels which may be problematic when no baseline is available. To score at the maximum, a child would have to be engaged in ''vigorous movement, including torso and head,'' which might not be characteristic of a child whose response to pain is mainly guarding and rigidity. These limitations might require discussion in studies employing the COMFORT scale [8].

The BPS (Behavior Pain Scale)

The BPS (Behavior Pain Scale) could be used for sedated and ventilated patients , but also adapted

to non-mechanically ventilated, non- intubated critically ill patients unable to self-report their pain. BPS-NI (Behavior Pain Scale in Non Intubated patient) is a valid, reliable and responsive instrument to measure pain in this population.

The BPS-NI and a Confusion Assessment score for the ICU could be used together to assess the patient's pain and confusion, respectively [9-10].

In addition to these psychometric properties, the BPS showed good feasibility, and average time of assessment is only four minutes. The short time required will make the BPS suitable for everyday clinical use. This instrument might prove useful to measure pain in uncommunicative critically ill patients and to evaluate the effectiveness of analgesic treatment and adapt it.

The Critical-Care Pain Observation Tool (CPOT)

The Critical-Care Pain Observation Tool (CPOT) showed that no matter their level of consciousness, critically ill adult patients react to a noxious stimulus by expressing different behaviors that may be associated with pain.

Therefore, the tool could be used to assess the effect of various measures for the management of pain.

The CPOT, developed in French, has 4 sections, each with different behavioral categories: facial expression, body movements, muscle tension, and compliance with the ventilator for intubated patients or vocalization for extubated patients.

Three testing periods, were completed during each patient's early postoperative course, and each testing periods included 3 assessments times for a total of 9 pain assessments scores obteined with the CPOT .

CPOT scores were higher during the positioning procedure than during rest or recovery). When patients were intubated during the second testing period, CPOT scores differed significantly between those who reported pain and those who did not. Moreover, when patients were extubated during the third testing period, the higher a patient's self- report of pain was, the higher was the patient's score on the CPOT.

Discriminant validity was supported by the finding that CPOT scores were higher during positioning than at rest in the 3 testing periods. Payen et al. also found higher behavioral scores during positioning than at rest in unconscious critically ill patients. Such results emphasize that pain behaviors are observable even if a patient cannot report pain [11].

Conclusions

Evaluation of pain in ICU patients is usually not a simple task. Although not simple, it is essential. Some patients are unable to provide a self-report or may be impaired by disease or treatments. These patients are at high risk for unrecognized pain. The appropriate treatment of pain is based on a clinician-performed pain evaluation process that is as accurate and detailed as possible.

ICU clinicians are encouraged to select pain evaluation methods using a hierarchical approach [12] .

Behavioral indicators can be a valid and reliable measure of pain, and allow to improve pain assessment and treatment for patients. Compliance with mechanical ventilation, adapted from the Comfort scale , had a moderate but effective contribution to pain assessment. Facial expression is well related to pain intensity. Use of combinated behavioral sclaes can improve pain asessment.

PAIN PATHOPHYSIOLOGY: AN UPDATE BY FUNCTIONAL MAGNETIC RESONANCE

K. Abdalla, E. Santangelo, R. Privitera, S. Shrod.

Anesthesia and Oncological Intensive Care Department, "T.Campanella" Cancer Center, UMG Catanzaro. School of Medicine - University "Magna Grecia" of Catanzaro.

Functional brain imaging with magnetic resonance imaging has been used extensively to map regional changes in brain activity. The signal used by this technique is based on changes in local circulation and metabolism (brain work) [1].
Hemoglobin is diamagnetic when oxygenated but paramagnetic when deoxygenated. The magnetic resonance (MR) signal of blood is therefore slightly different depending on the level of oxygenation. These differential signals can be detected using an appropriate MR pulse sequence as blood-oxygen-level dependent (BOLD) contrast. Higher BOLD signal intensities arise from increases in the concentration of oxygenated hemoglobin since the blood magnetic susceptibility now more closely matches the tissue magnetic susceptibility. By collecting data in an MRI scanner with parameters sensitive to changes in magnetic susceptibility one can assess changes in BOLD contrast. These changes can be either positive or negative depending upon the relative changes in both regional cerebral blood flow (rCBF) and oxygen consumption. Increases in rCBF that outstrip changes in oxygen consumption will lead to increased BOLD signal, conversely decreases in rCBF that outstrip changes in oxygen consumption will cause decreased BOLD signal intensity [2].
Anatomically pain is a complex entity involving multiple ascending pathways, different functional projections to thalamus, and a cortical circuit comprising areas, which although playing a specific functional role, participate in pain processing in serial and parallel manner [3].
The perception of pain is complicated and involves numerous areas through both the peripheral and central nervous systems. The spinothalamic, spinoreticular, spinomesencephalic, cervicothalamic, and spinohypothalamic tracts carry painful sensations to the amygdala, the periaqueductal gray, and the thalamus, which then connects to the insular cortex, the primary somatosensory cortex, the basal ganglia, the motor cortex, and the posterior parietal cortex [4,5].
When nociceptive stimulations reach the thalamus and limbic levels, the percept known as pain begins to arise. This percept has three components: affective–motivational, sensory–discriminative, and cognitive–evaluative [6].
The study of pain is improving because new techniques that scientists can use to define brain areas involved in the pain processing, one of these techniques is the functional magnetic resonance imaging (fMRI). With the reporting of pain being so subjective and patients' accounts sometimes being called into question, the researchers set out to test a means of objectively determining whether someone is experiencing pain or not by analyzing images from the brain.
Several studies examine pain-related activation in the brain have consistently found that, under normal conditions, several cortical structures, including primary and secondary somatosensory areas (SI and SII), the insular cortex (IC), and the anterior cingulate cortex (ACC), display levels of activation that parallel the intensity of the stimulus and the intensity of pain perceived [7-9]. In addition, some of these areas, such as the ACC and possibly part of the insula, appear to be more strongly associated with affective dimension of pain [9-11], findings that do not preclude a role for these structures in the coding of intensity, because the perception of pain intensity and affect are often highly correlated [12].
The increases in rCBF to noxious stimuli are almost constantly observed in SII and insular regions, and in the ACC, and with slightly less consistency in the contralateral thalamus and the SI. Activation of the lateral thalamus, SI, SII and insula are thought to be related to the sensory-discriminative aspects of pain processing. SI is activated in roughly half of the studies, and the probability of obtaining SI activation appears related to the total amount of body surface stimulated (spatial summation) and probably also by temporal summation and attention to the stimulus.

In a number of studies, the thalamic response was bilateral, probably reflecting generalized arousal in reaction to pain. ACC does not seem to be involved in coding stimulus intensity or location but appears to participate in both the affective and attentional concomitants of pain sensation, as well as in response selection. ACC subdivisions activated by painful stimuli partially overlap those activated in orienting and target detection tasks, but are distinct from those activated in tests involving sustained attention.

In addition to ACC, increased blood flow in the posterior parietal and prefrontal cortices is thought to reflect attentional and memory networks activated by noxious stimulation. Less noted but frequent activation concerns motor-related areas such as the striatum, cerebellum and supplementary motor area, as well as regions involved in pain control such as the periaqueductal grey.

In patients, chronic spontaneous pain is associated with decreased resting rCBF in contralateral thalamus, which may be reverted by analgesic procedures. Abnormal pain evoked by innocuous stimuli (allodynia) has been associated with amplification of the thalamic, insular and SII responses, concomitant to a paradoxical rCBF decrease in ACC. It is argued that imaging studies of allodynia should be encouraged in order to understand central reorganizations leading to abnormal cortical pain processing. A number of brain areas activated by acute pain, particularly the thalamus and anterior cingulate, also show increases in rCBF during analgesic procedures.

Taken together, these data suggest that hemodynamic responses to pain reflect simultaneously the sensory, cognitive and affective dimensions of pain, and that the same structure may both respond to pain and participate in pain control [13].

fMRI has demonstrated an altered state in the brain in chronic pain conditions including back pain and neuropathic pain [14]. There is a possibility of differences in the cerebral activation pattern in chronic pathological pain and experimentally induced acute pain. The brain activation pattern in chronic pain emphasizes the emotional aspect, whereas acute experimental pain seems to include localization or discrimination components [15].

In conclusion, the rapid developments of imaging methods over the past years have led to a decrease in variability in the description of central pain responses between different studies and have led to a definition of a central pain matrix with specialized subfunctions in human.

MOTOR CORTEX STIMULATION (MCS) AND DEEP BRAIN STIMULATION (DBS) FOR TREATMENT OF PAIN SYNDROMES

Angelo Lavano
Neurosurgical Department/Unit of Functional Neurosurgery, Campus "S. Venuta", University "Magna Graecia" of Catanzaro, Italy

Electrical stimulation of the brain is a tool for the treatment of chronic pain states that do not respond to less invasive or conservative treatment options as neuropathic pain or mixed nocipeptive/neuropathic pain: those types of pain corresponds to heterogeneous clinical syndromes that are secondary to a wide variety of peripheral and/or central nervous system injuries.
The brain may be stimulated with two procedures: stimulation of deep brain regions (DBS) (3,4) and direct stimulation of cortical areas (MCS) (1,2,5). Stimulation involves the implantation of electrodes together with the insertion of internal pulse generators (IPGs) subcutaneously in thoracic region that drive the overall system.

Deep Brain Stimulation

For the DBS multicontact wire-electrodes are implanted with stereotactic method in somatosensory thalamus (VPL/VPM) (4), in periventricular gray region (PVG), in postero-medial hypothalamus (PMH) (3) (Fig. 1).

Lead implantation is performed after induction of local anesthesia with intravenous analgosedation (remifentanil an propofol), stereotactic frame fixation and target localization performed with volumetric stereotactic CT images fused with T1-weighted MRI images. By means of a precoronal burr hole the lead is implanted into the target but accurate target localization and identification with intraoperative neurophysiological techniques are the key requirement for success and long-term results. This target refinement is performed using intraoperative microelectode recording as well as micro and macrostimulation. Intraoperative microrecording shows the tipical neuronal activity of each target while micro and macrostimulation evocs intraoperative responces
Stimulation in the lateral somatosensory thalamus elicits paresthesias in different body areas according to the laterality of the implanted electrode and suprathreshold stimulation is reported to be painful by the patients expecially in those with thalamic pain. Stimulation in the PVG creates a feeling of warmth, floating, dizziness panic and an reproducible elevation of blood pressure and heart rate at the threshold stimulation. Stimulation in postero-medial hypothalamus produces ocular deviation toward the stimulated side and a sensation of fear and panic. After placing the lead into the intended target the wire is connected to external extension lead for a postoperative testing trial for approximately 7 days. If during this trial a satisfactory pain relief is obtained the extension is internalized and it is connected to a pulse generator implanted subcutaneously in subclavicular region.

Fig. 1: Deep Brain Stimulation

Complications

All deep-brain electrode implantation procedures carry a small risk of mortality or post-operative neurological deficits due to intracerebral haemorrhage; others possible complications are infection or breakage of the hardware (4).

Indications for the deep brain stimulation

- DBS of thalamus and periventricular gray region: Failed-Back Surgery Syndrome (FBSS), Complex Regional Pain Syndrome (CRPS II), Trigeminal neurophatic pain and Dysestesia Dolorosa, Phantom-Limb Pain, spinal cord injury or post-stroke pain. In FBSS PVG stimulation is recommended for low-back pain whereas VPL stimulation mainly for radicular neuropathic pain component.
- DBS of hypothalamus: Painful syndrome of the face like Chronic Cluster Headache (CCH) and Short-lasting Unilateral Neuralgiform Headache with Conjunctival iniection and Tearing (SUNCT). The rationale for target choice was derived from Positron Emission Tomography examination which showed focal activation of the posteromedial hypothalamus during cluster headaches attacks. So the goal of high frequency stimulation of the postero-medial hypothalamus was to induce an electrical field inhibiting the focal hyperactivity of hypothalamic neurons responsible of cluster headache attacks.

Results

In our experience in thalamus and periventricular gray implants better result are obtained in patient with partial deafferentation pain (FBSS and CRPS II) than in patients with complete deafferentation pain (spinal cord injury or post-stroke pain)

The results of hypothalamic implants are very encouraging: most patients achieved stable and notable pain reduction and many became pain free.

Motor Cortex Stimulation

For MCS a multicontact plate-electrode is implanted in the epidural cranial space on primary Motor Cortex (M1) through a burr hole after application of local anesthetic or through a craniotomy after induction of either local or general anesthesia. The key point of this procedure is the accurate placement of the electrode over the motor cortex that somatotopically corresponds to the painful area. The best electrode orientation is perpendicular to the central sulcus. Image-guided MRI neuronavigation integrated with functional MRI (fMRI) into the targeting plan is used for precise identification of the Motor Cortex pre and intraoperatively (2). The main body segments and their respective motor cortex areas to be stimulated are:

1) face: lower part of the central gyrus,
2) upper limb and hand: middle part of the central gyrus between the inferior frontal sulcus and the superior frontal sulcus,
3) lower lim and trunk: upper part of the central gyrus between the superior frontal sulcus and the interhemispheric fissure.

The distal part of the lower limb lies on the inner surface of the hemisphere and therefore it cannot be directly stimulated epidurally; this limb representation, however, can be extended to the upper part of the motor gyrus.

Proper placement is confirmed with physiological testing: intraoperative neurophysiologic localization of M1 is performed with PESS (N20/P20 phase reversal) and with macrostimulation (hand clonic movements with 200-500 microsec, 5 Hz, increasing amplitude). An empirical approach is used to select the optimal stimulation parameters by adjusting the combination of contacts, polarity, frequency, pulse width and amplitude according to the patient's pain relief. Stimulation is always subthreshold for muscle contraction or any sensation. The most used stimulation parameters programmed on the pulse generator are: amplitude 2,5-6 V, pulse width 150-200msec, frequency 20-50Hz, 3+/0- setting, continuous or cycling mode. Amplitudes above 6

V are more likely to be associated with seizures during programming. MCS produces a period of poststimulus pain relief that can range from minutes to hours so the majority of surgerons report the use of a cycling mode of stimulation.
The amount of cerebrospinal fluid (CSF) between the dura and the cortex underneath the stimulating electrode is the most important factor affecting the distribution of the electrical field.

Fig. 2: Motor Cortex Stimulation

Complications
Like any neurosurgical procedure, MCS can be associated with risks and complications, including stimulation-induced seizures, epidural hematomas, infection or breakage of the hardware but the percentage of occurrence is very low about 3% (2). Sometime headache is provoked by stimulation but it disappears with parameter adjustments.
After the initial benefit, which may last for several months, sometimes there is a tolerance-like phenomenon with decrease or loss of efficacy. This phenomenon may be due to a scar formation around the plate electrode or to a neural plasticity and reorganization of the deafferentaded cortical area.

Indications for the motor cortex stimulation
MCS was proposed by Tsubokawa in 1991 for the treatment of central post-stroke pain. Since that time the indications increased and now include trigeminal neuropathic pain, postherpetic neuralgia, peripheral deafferentation pain syndromes such as brachial plexus and roots avulsions, spinal cord injury pain, phantom limb and stump pain, and complex regional pain syndrome (CPRS).

Results
Concerning Motor cortex implants nearly 60% of the treated patients improved with a higher than 50% pain relief after several months of follow-up and sometimes of a few years. Better results are obtained in facial neuropathic pain (more than 80% of successful results) rather than in no-facial pain: the large somatotopic facial representation on the motor cortex compared to the other body regions, may be an explanation for these particularly good results.

Mechanism of action
Under normal conditions noxious and non-noxious inputs from the thalamus converge at cortical level and the non-noxious stimulus is able to inhibit the noxious afferences. When such an inhibitory mechanism is lost as a consequence of a thalamic lesion, MCS can antidromically and orthodromically activate large fibres reciprocal connections between the motor and the sensory cortex, and then activate non-noxious, fourth order sensory neurons restoring the inhibitory control

over tha nocicptive inputs. PET studies demonstrated a significant increase in cerebral blood flow in the ipsilateral thalamus, but also in the brainstem, cingulated gyrus, anterior insula and orbito-frontal cortex during MCS in patients reporting a good pain relief. MCS may reinforce the control of non-nociceptive sensory inputs on nociceptive systems not only at the thalamic level, but also at the brainstem and at the spinal cord level.
MCS may also reduce the emotional component of chronic pain by activating the anterior cingulated cortex and the anterior insula as demonstrated by PET studies.
Biochemical processes such as action on the endorphin sites in the brainstem or control on GABAergic interneurons at cortical level may also be implicated in the mechanisms of action.

Conclusions

DBS and MCS are helpful treatment options in patients with neuropathic/deafferentation pain that do not respond to less invasive or more conventional therapeutic measure. A neural substrate for the origin of pain should be obvious; patients with diffuse pain state without a detectable neural reason should be excluded; also pain in pelvic region do not respond. Before being referred to a neurosurgeon for MCS/DBS patients should be treated in a multidisciplinary pain team and with a sufficient amount of time with tricyclic antidepressants, anticonvulsivant and other medications.

ACUTE PAIN IN CHILDREN

G. Savoia, M. Loreto, A. Geri, C. Eziandio
UOSC of Anaesthesia and Pediatric Intensive Care - AORN "A. Cardarelli"-Naples
corresponding: gennarosavoia@libero.it

Pain is an unpleasant physical and psychological experience which if not managed appropriately in children can lead to distress, clinical deterioration and severe functional limitations. Pain can be associated with numerous paediatric diseases and conditions and is an important consideration in children undergoing procedures and surgery. Acute pain in children is still undertreated in many hospitals. This seems to be related mainly to organizational aspects. Control of Pain in Children can be quite difficult as it hard to determine the exact level of pain present. In addition, many of the medications used to treat pain have not been appropriately tested in children so doctors may not be entirely sure of their effects and be reluctant to use them. In the past, pain has been poorly managed in paediatric patients due to the false belief that neonates and children do not experience pain or require pain relief, as commonly as adults. It was thought that neonates did not experience or remember pain due to their immature nervous systems. Subsequent studies showed these responses develop much earlier than expected. Furthermore, several studies have highlighted that many health professionals underestimate the level of pain experienced by young children. More recent studies have confirmed the benefits of appropriate pain relief in young patients and that neonates, infants, and children can receive analgesia and anesthesia safely if the necessary dosing and administration adjustments are made. Inadequate management of pain, particularly chronic forms can have substantial impacts on children. A recent study proved that chronic pain in children and adolescents can cause considerable functional limitations, particularly school absenteeism, sleep disturbance and inability to perform sporting activities. Ongoing absences from school due to pain can lead to poor school performance and long-term complications. Pain in the acute setting can lead to deterioration in the patient's clinical condition (1 - 5).

Pain assessment

Infants and young children cannot verbalise their pain levels so rely on adult's and health professional's interpretations of external manifestations of the pain. Difficulties assessing pain have lead to the development of numerous pain assessment scales that health professionals use to grade patient's pain. These look at behaviour pattern and what the child reports as their level of pain. There are different tools for different age groups. Children older than eight years of age can usually describe their pain similar to adults by rating it according to the intensity of pain on a horizontal ruler. For younger children, doctors use series of faces and pictures (progressively becoming more distressed) which the child can point to identify their pain level. Neonates, infants and children under four years are assessed based on observation of behaviour and physiologic changes such as facial expressions, motor expressions, verbal responses and vital signs (such as pulse, blood pressure etc). The assessment tools are not entirely reliable but usually give the medical staff a sufficient idea of whether pain is present and how severe so they can treat it appropriately.

Pain treatment

There are numerous options available for paediatric pain management outlined below. In general, a multidisciplinary approach (that is using several different agents such as drugs and other techniques in combination) has been proven to be the most beneficial.The pain control can be achieved through the use of analgesics given by different administration routes, combined to sedation or general anaesthesia, using non pharmacologic methods.Regional anaesthesia is gaining popularity in infants and children. The addition of ultrasound guidance has broadened the potential indication and improved the efficacy of nerve blocks in this populations of patients (6 -9).

Concerning more severe procedures (lumbar puncture, bone marrow aspiration), the administration of vapour anaesthetic and of a topical or local anaesthetic infiltration is effective in most of the patients. For major procedures (fracture reduction), intravenous regional blocks using a local

anaesthetic is effective in most of the paediatric patients; despite the potential complications and the high incidence of adverse events, the general anaesthesia can be more appropriate in selected groups of patients. The PCA system is very safe and effective, and can be used in cooperative children (usually > 5 years of age). In day-surgery procedures, the wound infiltration with local anaesthetic, the caudal block or the peripheral nerve blocks (block of dorsal nerve of penis for fimosis, block of ilioinguinal/iliohypogastric nerve for hernia) assure a good level of analgesia (2, 10 -11).

Paracetamol and FANS

Acetaminophen and NSAIDs can be used for the treatment of moderate pain and can reduce the need of opiates after major surgery . Acetylsalicylic acid must be carefully used in febrile children due to the potential risk of Reye syndrome; furthermore, aspirin and NSAIDs can increase the risk of postoperative bleeding; serious adverse events are rare in children aged > 6 months.Acetaminophen (paracetamol) is probably the most commonly used analgesic as it is very safe. Ready-to-use i.v. paracetamol (1 g solution, dose=15 mg/Kg), used as monotherapy or in combination with other analgesics, may be effective for alleviating postoperative pain and well tolerated in patients undergoing ambulatory surgery (12 -14).Non-steroidal anti-inflammatory drugs (such as ibuprofen and naproxen) are also used in children. In general, these agents are given orally which is the preferred route of administration for most patients. A combination of individually titrated intraoperative opioids and regularly administered perioperative mild analgesics (NSAID and/or paracetamol) is required for management of postoperative pain.

Opioids

Opioids are stronger drugs used for more severe pain such as that associated with surgery or chronic cancer. Morphine, fentanyl, codeine and meperidine (pethidine) may be administered by various routes. In some cases the drug can be given intravenously (into the veins and bloodstream) and may be connected to a special pump. The patient can press a button to get a dose of medication as required. This is called 'patient controlled analgesia' and is a good method of administering pain medications due to the highly varied doses needed to get appropriate pain relief. It has been used in children as young as six years. The machine has special cut off values so the patient is unable to overdose by pressing the button too much. In other cases the nurse or parent may control the doses. It should be recognized that infants less than 3 months old and neonates and infants with lung disease are at particular risk of respiratory depression from some of these drugs. This is because accumulation of the drug causes inhibition of the breathing centers in the brain. Caution must always be taken giving these types of drugs to young patients (15).

Local anaesthetics

As far as minor procedures are concerned (venipuncture, stitches, etc), the administration of vapour anaesthetic and/or of a topical local anaesthetic, as EMLA, can be considered a safe and efficacious procedure. Local anaesthetics such as lidocaine and bupivacaine, are widely used in children undergoing procedures (16). They have a narrow dose for which they are effective without causing side effects. Maximum doses of both drugs should not be exceeded or toxic side effects will occur. Other analgesic techniques include blocking particular nerves to stop the pain signal.

Others

Tricyclic antidepressants and anti-epileptic medications can be used in the management of neuropathic pain (pain originating from damage or irritation to a nerve pathway). Numerous sedative drugs are also used in children undergoing surgery and other procedures. However, these drugs are more to treat anxiety than pain per se but they are worth a mention. Chloral hydrate, benzodiazepines (especially midazolam), ketamine, barbiturates and nitrous oxide are the main sedative agents used in pediatrics. The safety of sedation in children has greatly increased over the years particularly when agents were developed that could reverse some of the respiratory depressive actions of the above drugs (4, 5).

Non-pharmacological

Non-pharmacological agents are often used in combination with the drug classes already mentioned in the management of chronic pain:

- Hypnosis has been proven beneficial in clinical studies.
- Cognitive Behavioral therapy- There is also good evidence for this treatment.
- Deep breathing and relaxation exercises.
- Distraction techniques- Focusing a child's attention away from something negative to something more positive such as music, toys or bubbles.
- Play therapy.
- Friendly hospital environment- This can reduce anxiety and fear in young patients which has been shown to exacerbate pain.
- Pain in neonates can be helped by breast feeding, sugars, pacifiers and multisensory stimulation of your baby (e.g. massage, voice, eye contact).
- Education- If your child is adequately described the details and nature of a procedure (including being shown equipment and being allowed to ask questions) it can reduce their fear and help reduce pain. Only necessary procedures should be performed on your child.
- Parent training programs- It can help your child if you are taught ways to identify and cope with pain so you are able to offer positive support.

Conclusion

A subject of considerable interest recently is the discovery that the experience of pain in early life may lead to long-term consequences. New research findings from laboratory and clinical studies have clearly identified possible mechanisms and provided evidence that long-term behavioral changes can extend far beyond what would be considered the normal period of postinjury recovery. Timing, degree of injury, and administered analgesia and its nature may be important determinants of the long-term outcome of infant pain. Chronic pain, including neuropathic pain, is far more common in children than was thought(16). The assessment and treatment of this pain and its functional consequences present a considerable unmet challenge. There is a pressing need for further research and clinical development in the management of pain in children.

CANCER PAIN TREATMENT

Aniello De Nicola and Maria José Sucre
Dept. of Anaesthesia and Intensive Care, San Leonardo Hospital, Castellammare di Stabia (NA)

Cancer-related pain is a major issue of healthcare systems worldwide. The reported incidence, considering all stages of the disease, is 51%, which can increase to 90% in the advanced and terminal stages. For advanced cancer, pain is moderate to severe in about 40–50% and very severe or excruciating in 25–30% of cases (1).
Pain management is still given too little attention by health professionals. Throughout the spectrum of health care, including cancer centers, intensive care units, and nursing homes, cancer pain continues to be both prevalent and undertreated.
Pain depends on many factors such as the type of cancer, the stage of the disease, and the patient's tolerance. Cancer pain can result from the following:

- Blocked blood vessels causing poor circulation
- Bone fracture from metastasis
- Infection
- Inflammation
- Psychological or emotional problems
- Side effects from cancer treatments (e.g., chemotherapy, radiation)
- Tumor exerting pressure on a nerve

Initially, pain may produce physiological signs such as grimacing, rapid heart rate, sweating, and rapid breathing. Patients with pain lasting more than 3 months (chronic pain) often do not display physiological signs and as a result, chronic pain often is undertreated. When possible, cancer pain is treated by removing or reducing the tumor that is causing it. When the tumor cannot be removed, the pain can be treated in various ways.
Studies have shown that 90% of patients with advanced cancer experience severe pain and that pain occurs in 30% of all cancer patients, regardless of the stage of the disease. As many as 50% of patients may be undertreated for cancer pain, yet not all cancer patients feel pain, and pain is rarely a sign of early cancer. Pain usually increases as cancer progresses.
The most common cancer pain is from tumors that metastasize to the bone. As many as 60-80% of cancer patients with bone metastasis experience pain. The second most common cancer pain is caused by tumors infiltrating the nerve and hollow viscus. Tumors near neural structures may cause the most severe pain. The third most common pain associated with cancer occurs as a result of chemotherapy, radiation, or surgery (2).
Cancer pain also may occur in different parts of the body. In one study, more than 80% of patients experienced two distinct pains, and more than 30% experienced three distinct pains.
Effectively treating chronic pain poses a great challenge for physicians. This type of pain often affects a person's life in many ways. It can change someone's personality, ability to function, and quality of life.
The assessment may reveal a cause for the pain that is amenable to primary therapy. For pain produced by tumor infiltration or compression, antineoplastic treatment with surgery, radiation therapy, chemotherapy, or other approaches may be considered. Pain caused by infections may be amenable to antibiotic therapy or drainage procedures
The WHO in 1986 established a stepladder approach for the treatment of patients with cancer pain. Clearly, the WHO method has been of enormous benefit for the treatment of cancer pain worldwide. Several case series document that the application of this analgesic regimen will achieve pain relief in the majority of patients with cancer. Between 70–90% of patients with cancer pain, treated according to the three-step ladder, achieve effective analgesia (3)
While the use of non-opioids for step I and "strong" opioids for step III is widely accepted, the clinical usefulness of the "weak" opioids in the management of cancer pain has been challenged.

There are two systematic reviews comparing the efficacy of non steroidal anti-inflammatory drugs (NSAID) versus a weak opioid (4). The results suggest that the transition from step I to step II drugs does not necessarily improve analgesia. Furthermore, this transition may delay achieving optimal pain control, especially in patients with rapidly progressive pain or in those who need quick titration of analgesic therapy.

The World Health Organization Three-Step Analgesic Ladder provides a useful approach to drug selection for cancer pain:

- At step 1, patients with mild to moderate cancer-related pain should be treated with a nonopioid analgesic, which should be combined with adjuvant drugs if a specific indication for one exists (5).
- At step 2, patients who have limited opioid exposure and present with moderate to severe pain or who fail to achieve adequate relief after a trial of a nonopioid analgesic should be treated with an opioid conventionally used for moderate pain'(previously termed "weak" opioids). In the United States, these drugs include codeine, hydrocodone, dihydrocodeine, oxycodone, or propoxyphene. This drug is typically combined with a nonopioid and may be coadministered with an adjuvant analgesic.
- At step 3, patients who present with severe pain or who fail to achieve adequate relief following appropriate administration of drugs on the second step of the analgesic ladder should receive an opioid conventionally used for severe pain (previously termed "strong" opioids). These drugs (morphine, oxycodone, hydromorphone, methadone, and fentanyl) may also be combined with a nonopioid analgesic or an adjuvant drug (6,7).

Acetaminophen (paracetamol) or nonsteroidal anti-inflammatory drugs (NSAIDs) are effective analgesics for patients with mild cancer pain and can be combined with opioids in patients with moderate to severe pain (5). Experience with the use of the WHO ladder has shown that the simple principle of escalating from non-opioid to strong opioid analgesics is safe and effective. In most patients, side effects associated with the use of opioids can be easily managed with a combination of patient education and reassurance about the transient nature of sedation and emesis, careful selection of dose and route of opioid, and the use of additional drugs such as antiemetics and laxatives.

Opioids should be administered by the least invasive and most convenient route capable of providing adequate analgesia for the patient. In routine practice, the oral route is usually the most appropriate. Alternative noninvasive routes, including sublingual, and transdermal, are sometimes feasible for patients who have impaired swallowing or gastrointestinal obstruction.

Opioids are the gold-standard treatment in moderate to severe pain. Numerous studies have shown that when the WHO treatment guidelines are followed, 90% of patients are pain-free. These pain management guidelines suggest that the choice of analgesic pharmacotherapy should be based on the intensity of pain reported by the patient, not simply on its specific etiology. In the WHO guidelines, morphine remains a cornerstone for the management of cancer pain. A substantial minority of patients treated with oral morphine (10–30%) do not have a successful outcome because of excessive adverse effects, inadequate analgesia, or a combination of both adverse effects together with inadequate analgesia. It is now recognized that individual patients vary greatly in their response to different opioids. Patients who obtain poor analgesic efficacy or tolerability with one opioid will frequently tolerate another opioid. Opioids, such as morphine, hydromorphone, oxycodone, fentanyl, and buprenorphine, have been shown to be highly effective in alleviating moderate to severe malignant pain (7).

Recently, the development of new drugs and formulations of different opioids has enlarged the available therapeutic arsenal and improved their administration, thus contributing to better tolerance of side effects. This has modified the third step in analgesia, and morphine does not remain the first-choice drug. Experience with the use of the WHO ladder has shown that the simple principle of escalating from non-opioid to strong opioid analgesics is safe and effective. However, the role of the weak opioids in the treatment of moderate cancer pain has been questioned, and some experts

speculate that this second step of the ladder could be omitted (8).
Morphine remains the gold standard among strong opioids and is the first-line recommended treatment in moderate to severe cancer pain. Absorption is well achieved through the gastrointestinal tract, but its bioavailability is variable (15–65%) due to a first-step effect that depends on the speed of its metabolization in liver. Serum levels have a peak at approximately one hour. Clearance is variable and medium elimination half-life ranges from 3–4 hours (1–7). This determines the way of administration.
Doses need to be individualized, depending on every single patient's pain baseline and previous analgesic requirements. In order to assess the morphine requirements, 5–10 mg of immediate-release morphine sulphate, up to once every four hours, should be administered until pain control is adequate during at least 48 hours. Then, we should convert the total daily dose to controlled-release morphine sulphate administered twice a day, every 12 hours. As a rescue treatment, one sixth of the total daily oral morphine requirements should be administered every four hours as immediate-release morphine.
During lastyears a wide range of fentanyl preparations are becoming available, including buccal tablets or patches, nasal sprays, inhalers, and active transdermal patches (heat or electrical). Some of these presentations, such as nasal sprays and inhalers, may result in a rapid response. In addition, the expense of some of these appliances may greatly reduce their cost-effectiveness.
Oral Transmucosal Fentanyl Citrate was approved in Europe for breakthrough pain in cancer patients who were undergoing an opioid-based treatment for their pain problem (9,10).
Fentanyl Iontophoretic Transdermal System has been authorized for the European Union since 2006, and is indicated for the treatment of postsurgical pain from moderate to severe. The system consists of a compact electronic controller and two reservoirs containing hydrogel, one of which contains fentanyl in gel, with no needles and on-demand. It releases from 40 μg per dose on demand, until a maximum of 240 μg per hour (six doses, 10 minutes each) and no more than 80 doses in a 24-hour term (11).
Fentanyl Buccal Tablet employs an innovative drug delivery system, to optimize the delivery of fentanyl across the buccal mucosa. When FBT comes in contact with saliva, it generates an effervescent reaction, which enhances the rate and extent of fentanyl absorbed through the buccal mucosa (12,13).
Fentanyl Sublingual Tablet is a new tablet system for sublingual administration and rapid drug absorption: promotes rapid absorption and high bioavailability, with subsequent almost immediate onset of pharmacologic effect. However, many oromucosal delivery systems are compromised by the possibility of the patient swallowing the active substance before it has been released and absorbed locally into the systemic circulation..
Fentanyl Citrate Nasal Spray For the treatment of breakthrough cancer pain, the inhaler is an ideal drug-delivery system that can provide a noninvasive route of administration and still maintain rapid drug delivery.
Parenteral routes of administration should be considered for patients who have impaired swallowing or gastrointestinal obstruction, those who require the rapid onset of analgesia, and patients who require high doses that cannot otherwise be conveniently administered. Continuous infusions, via elastomeric pumps, avoid the problems associated with the bolus effect and may be administered IV or SC. If continuous IV infusion must be continued on a long-term basis, a permanent central venous port is recommended.
Continuous infusions of drug combinations may be indicated when pain is accompanied by nausea, anxiety, or agitation. In such cases, an antiemetic, neuroleptic, or anxiolytic may be combined with an opioid, provided it is nonirritant, miscible, and stable in combined solution.
During long-term treatment, it is often necessary to switch routes of administration. All such changes require careful attention to relative potency. It is generally prudent to perform the switch in a gradual stepwise manner over a two to three-day period.
Barriers to good cancer pain management may be related to health practitioners, to patients, or to

the health care systems.

Physicians have acknowledged that they are not properly trained in pain assessment and may not address the issue of pain unless it is raised by the patient. To provide adequate pain control, health professionals need to seek a patient's report of pain as the primary assessment. Many cancer patients fear that reporting pain will distract clinicians from treating their disease and therefore do not report it.

Inclusive pain assessment and management are poorly rewarded as they are time consuming. Cost can be a factor in relation to other issues including the availability of medications. Most cancer patients should be able to have their pain managed as an outpatient.

Patient attitudes about pain and its treatment can inhibit adequate pain management. Specific issues included fear of addiction, beliefs that "good" patients do not complain about pain, and concerns about side effects. Some patients felt that doctors were not interested in their pain, over half were concerned about addiction, and most were anxious about constipation as a side effect of cancer pain management. There were more concerns in those with less education, lower incomes, and higher levels of pain and in those who were undermedicated.

Fear of addiction is a special concern for older patients and may also be a concern for their families and health care providers. There is little rational evidence to support the fear of addiction(14). Confusion in the terminology associated with addiction and physical dependence may contribute to the problem. Physical dependence is a physiological phenomenon characterized by the development of an abstinence syndrome following abrupt discontinuation of therapy, substantial dose reduction, or the administration of an antagonist drug. Physical dependence will develop in patients who use opioids for any length of time in a situation similar to that of any patient who has been prescribed corticosteroids over time. When opioid use is stopped suddenly, the patient experiences physiological withdrawal symptoms that may include fever, tachycardia, and abdominal cramps. The onset of withdrawal symptoms has been used by many to establish the diagnosis of substance dependence. A more appropriate definition of addiction or psychological dependence allows the diagnosis to be made on the presence of three types of aberrant behavior:

- a patient's loss of control over drug use,
- a patient's compulsive use of the drug
- continued use of the drug despite evidence of harm to the patient. Publicity campaigns may contribute to the public's misunderstanding of these concerns.

Three components are critical to managing cancer pain: assessing pain, establishing an appropriate therapeutic opioid regimen, and integrating with other therapies. An appropriate therapeutic opioid regimen involves initiating, consolidating and maintaining therapy. Other strategies (eg, advanced pharmacological, adjuvant, interventional, and psychological) can be added to opioid therapy (15).

Pain is a symptom experienced by many cancer patients regardless of disease stage. To ensure proper management of cancer pain, physicians must recognize the components that affect pain relief, including the barriers to treatment of cancer pain and the factors that influence both the pharmacodynamics and the pharmacokinetics of analgesic agents. The management of pain in cancer patients should proceed aggressively with more frequent reassessment of both analgesia and side effects to ensure optimal cancer pain relief.

PAIN MANAGEMENT IN THE INTENSIVE CARE UNIT

Maria José Sucre and Aniello De Nicola
Dept. of Anaesthesia and Intensive Care, San Leonardo Hospital, Castellammare di Stabia, Italy

Introduction

New reports reviews the complex nature of pain experienced by a critical care patient and details the benefits of taking a comprehensive approach to pain management, one that combines pharmacotherapy with behavioral, social, and communication strategies, interdisciplinary teams, and family involvement.Patients in the ICU have unique characteristics that provide significant challenges for the critical care team. Critically ill patients may suffer disproportionately compared with other patients, experiencing significant pain from their life-threatening illness or injury, and additional pain associated with simple procedures, such as endotracheal suctioning or the removal of a chest tube. Furthermore, critically ill patients are often unable to effectively communicate pain to their caregivers, making it difficult to assess and manage pain sufficiently.

Organ failure, sepsis, and other medical complications can make it difficult to manage pain in the critically ill. The use of opioids or related medications is the standard method of acute pain control, and the choice of which opioid to use is carefully selected based on the uniqueness of each patient's pain management issues, as well as potential side effects and drug interactions.

Much of the research on pain medications has been conducted in non-ICU settings. The ICU clinician must extrapolate and apply this research to the care of critically ill patients who frequently have tenuous and rapidly changing clinical conditions that complicate pharmacotherapy decisions (1).

Tools for pain evaluation

Numerous scales to assess the level of consciousness exist. Regardless of the scale, patients should be able to maintain a level of wakeful, quiet comfort; have adequate control over pain and agitation; and be able to tolerate mechanical ventilation (2). The complex nature of caring for the critically ill, particularly in the area of pain management, requires a more holistic approach to patient care. Standard tools for pain assessment and evaluation, which typically rely on a patient's own verbal report, may be ineffective for critically ill patients who are unable to communicate(3). In these situations, the critical care team can use alternative methods for pain assessment, including the following:

- Patient Risk Profile. This tool identifies the patient's risk of pain prior to a procedure and allows the team to administer preemptive pain management, whereby decreasing the incidence of pain.
- Nonverbal Communication, Patients who cannot speak or have difficulty speaking may be able to point or blink when referring to a pain scale.
- Analgesic Trial. To verify the presence of pain, the ICU team can administer a low dose of first-line analgesic followed by observation of the patient's pain-related behaviors.

Dosing Strategies

Sedatives and analgesics may be given intermittently or by continuous infusion(4). If continuous infusion is used, scheduled daily interruptions should be performed. Daily interruption has been shown to reduce the duration of mechanical ventilation, length of ICU stay, ICU complications, and posttraumatic stress disorder (5). While beneficial, interrupted sedation may produce a catecholamine surge, and caution should be taken in patients with hypertensive crises, traumatic brain injuries, alcohol withdrawal, or unstable coronary artery disease. However, adverse cardiovascular effects are rare, even among high-risk patients.

Regardless of the chosen method of sedation, titration to the desired effect is critical. This remains the most challenging aspect of sedation, and its implementation remains controversial (6,7).

Analgesic and sedative agents

Midazolam is a potent and extremely short-acting benzodiazepine with an elimination half-life of only 2 hours. Midazolam is indicated for preoperative and procedural sedation and induction of

general anesthesia (8). It is also useful for short-term management of agitated delirium. It accumulates during continuous infusion causing persistent sedation, especially in the elderly and in patients with renal or hepatic dysfunction. Its use is contraindicated in patients who use alcohol as well as those with acute narrow-angle glaucoma or head injury.

Remifentanil is a potent, selective mu-opioid receptor agonist that is indicated for analgesia in mechanically ventilated patients and during induction and maintenance of general anesthesia. Its potency is similar to that of fentanyl, and its onset of action is approximately 1 minute (9). Unlike other hepatically metabolized synthetic opioids, remifentanil has an ester linkage that undergoes rapid hydrolysis by nonspecific tissue and plasma esterases, rendering it an inactive metabolite. Its elimination half-life is 10 minutes, allowing it to be easily titrated while minimizing tissue accumulation. However, this very short duration of effect lends itself to early tolerance. Remifentanil's unique pharmacologic profile makes its use very advantageous in patients with neurotrauma, renal impairment, and chronic obstructive pulmonary disease and in those undergoing cardiac or general surgery. Adverse effects include a dose-dependent reduction in sympathetic nervous system tone, respiratory depression, heart rate and arterial pressure. This adverse effects can minimized with accurate titration. In our opinion is the most advantageous drug for sedation and analgesia in ICU patients.

Propofol is a short-acting, intravenous, alkyl phenol with sedative and hypnotic properties. It has a rapid onset of action and short duration of effect, allowing for easy titration with limited accumulation. In addition, side effects are minimal and an absence of active metabolites make it an ideal agent for sedation in the ICU (10,11). Its onset of action is 30 seconds, distribution half-life 2-8 minutes, and elimination half-life between 2 and 24 hours. Its extensive peripheral tissue redistribution leads to a rapid decline of blood concentrations, thereby requiring continuous infusion for effective sedation. The presence of hepatic cirrhosis or renal insufficiency does not appear to significantly alter its pharmacokinetics. Propofol is used for sedation of mechanically ventilated patients (12,13). However, it provides no analgesia. The fast-onset, rapid awakening for neurologic assessments and ease of titration make the use of propofol advantageous over the longer-acting benzodiazepines (14). Hypotension and transient apnea are common side effects.

Dexmedetomidine is a centrally acting, alpha-2-receptor agonist. Although its mechanism of action is similar to that of clonidine, it has an 8-fold greater affinity for the alpha-2 receptors. It is unique in its ability to provide sedation without compromising respiratory drive or function (15). It has sedative, analgesic, sympatholytic, and anxiolytic effects that blunt many of the cardiovascular responses while reducing the anesthetic, sedative, and analgesic needs of the patient. Onset of action is 15 minutes, and it has a half-life of 2 hours. Dexmedetomidine does not have amnesic properties, which may be detrimental in patients requiring neuromuscular blockade (16,17). The most commonly reported adverse effects are primarily cardiac. Continuous infusion causes hypotension in approximately 30% of patients and can be associated with significant bradycardia. Several studies have assessed the safety and efficacy of dexmedetomidine (18,19)

Ketamine is a phencyclidine derivative, noncompetitive N-methyl-D-aspartate (NMDA)-receptor antagonist that produces sedation, hypnosis, analgesia, and amnesia. It is a dissociative agent that differs from most sedatives by producing a trancelike cataleptic state in which patients experience profound analgesia and amnesia but maintain cardiopulmonary stability (20). The effects of ketamine are not dose-dependent, once a critical threshold has been reached, the dissociative state occurs and additional drug does not augment this state. For intravenous formulations, the onset of action is 1-5 minutes. It has a duration of action of 30-45 minutes and an excretion half-life of 2-3 hours. Ketamine is 12% protein-bound and is rapidly distributed into brain and other well-perfused tissues. It is methylated to norketamine and then renally excreted. Ketamine is indicated for brief diagnostic and surgical procedures that have the potential to be painful and emotionally disturbing but do not require skeletal muscle relaxation. It is also indicated as an anesthetic induction agent before administration of other general anesthetic agents, and as an adjunct to low-potency agents, such as nitrous oxide. Ketamine produces a dose-related increase in heart rate and blood pressure

while preserving respiratory function, thereby minimizing the risk for cardiopulmonary compromise (21).

Conclusion

Although pain in the ICU is inevitable, there are a number of unique interventions that critical care professionals can use to anticipate, manage, and even prevent pain from occurring. Physicians, nurses, pharmacists, and other members of the extended critical care team should continue to make effective pain assessment and management a priority in the ICU.

Adequate sedation is a critical part of effective ICU medicine. Although several agents are available to aid in sedation, the optimal regimen has yet to be determined and should be tailored to the individual patient. While the strategy used in each patient varies, adequate analgesia and reduction of anxiety, agitation, motor activity, and work of breathing should remain the goal for each patient.

THORACIC EPIDURAL ANALGESIA

Carlo Di Iorio M.D., Head of the U.O.S.C. Anesthesia and I.C.U., AORN A. Cardarelli Napoli

The Author describe the thoracic epidural technique in thoracic surgery. Epidural anaesthesia and analgesia are widely and successfully used to alleviate perioperative pain. The technique claims to offer many advantages, such as improved cardio-pulmonary function, less intraoperative anaesthetic, improved postoperative gut function, early tracheal extubation, and better mobilisation. Moreover, there is an interest in the use of high thoracic epidural anaesthesia because experimental and clinical studies have suggested that central neuroaxial blockade attenuates the response to surgical stress and enables earlier extubation and a smoother postoperative course. Therefore, the Author illustrates these different aspects of this anaesthetic technique, and the anatomical features of the thoracic vertebral column. Finally, this contribution summarizes five years of experience in thoracic epidural technique.

L'ANALGESIA PERIDURALE TORACICA

L'inserzione di un catetere epidurale toracico per un blocco nervoso con oppioidi e/o anestetici locali è stata storicamente ed è tuttora ritenuta, non senza qualche ragione, come più difficoltosa dell'inserzione lombare.

I motivi sono fondamentalmente legati alla paura per il potenziale danno midollare, alle differenze anatomiche della regione toracica rispetto alla più usata regione lombare, che rendono più arduo l'accesso allo spazio epidurale, ed infine alle alterazioni della fisiologia cardiovascolare e respiratoria, prodotte dalla procedura e dai farmaci utilizzati (1).

CONSIDERAZIONI ANATOMICHE E CONSEGUENZE SULLA PROCEDURA

Alcune differenze anatomiche tra il rachide medio-toracico e lombare sono alla base del diverso approccio con ago nello spazio epidurale del primo distretto.

I processi spinosi delle vertebre toraciche medie hanno un'inclinazione caudale di 45°, più marcata tra T3 e T7, con un ristretto spazio interspinoso data l'embricatura degli elementi vertebrali, che richiede una profondità d'inserzione dell'ago epidurale maggiore rispetto alla zona lombare.

I processi spinosi di T1-T2 e di T10-T11-T12 sono quasi orizzontali, come a livello lombare, e richiedono l'inserzione dell'ago a circa 90°, rispetto al piano cutaneo, anche se essendo più corti dei processi spinosi lombari, l'ago incontra lo spazio peridurale ad una minore profondità.

Il margine inferiore dei processi spinosi medio-toracici corrisponde all'altezza della parte media della lamina della vertebra sottostante. Al disotto di T7 la situazione diventa progressivamente simile a quella di L1-L2.

Se l'ago è inserito troppo vicino al processo spinoso nell'accesso paramediano e ogni volta che si effettua la puntura sulla linea mediana, l'ago può urtare contro il processo spinoso. Tuttavia l'ostacolo più comune alla progressione dell'ago è la lamina vertebrale inclinata posteriormente e verso il basso.

Gli spazi toracici interlaminari sono sagomati a semiluna e più piccoli di quelli lombari, misurando in media 15 x 5mm, anche perché le lamine vertebrali sono più larghe, anche se più corte in altezza.

I legamenti interspinosi toracici sono meno ben definiti e più stretti rispetto ai lombari e più difficili da identificare perché i processi spinosi sono più vicini.

I legamenti gialli sono più sottili nella zona toracica (3-5mm) rispetto alla regione lombare (6mm), così che la sensazione tattile del passaggio dell'ago è più difficile da apprezzare. Da uno studio anatomico di Lirk si evidenzia che i legamenti gialli cervicali e toracici alti, fino a T4, presentano, con frequenza statisticamente significativa, soluzioni di continuità che rendono ancora più difficile percepire la resistenza alla progressione dell'ago (2).

Lo spazio epidurale varia inversamente al contenuto del canale spinale. Lo spazio epidurale è stretto in corrispondenza dei rigonfiamenti midollari cervicale, che va da C3 a T2, per la fuoriuscita delle radici dei plessi brachiali, e lombare, che va da T9 a L1, per la fuoriuscita delle radici dei

plessi lombari.
Nel tratto cervicale basso la distanza tra il legamento giallo e la dura madre è di 2mm o meno, al disotto di C7 lo spazio si allarga, soprattutto durante la flessione del collo, per raggiungere 3-4mm a livello di T1. Nella regione toracica media è di 3-5mm ma molto sottile lateralmente, al di sotto di L2, dove finisce il midollo, è di 5-7mm.
Pertanto la quantità di anestetico locale, richiesta per un blocco di un segmento midollare, è direttamente proporzionale all'area traversa dello spazio epidurale: approssimativamente 0,5-0,8ml per un segmento toracico, 1,5ml per un segmento lombare, 3ml per un segmento sacrale.
I forami di coniugazione a livello toracico sono più stretti, rispetto al livello lombare, per cui è minore la diffusione laterale della soluzione anestetica locale e quindi dei 2 meccanismi responsabili dell'anestesia peridurale (blocco delle radici spinali a livello della cuffia durale e blocco nervoso paravertebrale per la diffusione attraverso i forami di coniugazione) a livello toracico il primo prevale di gran lunga sul secondo.
Nell'adulto ***il midollo*** è più corto rispetto alla colonna vertebrale per cui i segmenti midollari non si trovano esattamente in corrispondenza delle vertebre omonime. Infatti gli 8 segmenti cervicali si trovano compresi tra le prime 6 vertebre cervicali, i primi 6 segmenti toracici vanno da C7 a T4, gli ultimi 6 segmenti toracici vanno da T5 a T9, i 5 segmenti lombari vanno da T10 a T12, i cinque segmenti sacrali ed il singolo coccigeo vanno da T12 a L1.
L'ottavo nervo cervicale emerge tra C7 e T1, gli altri nervi cervicali emergono al di sopra della vertebra corrispondente. I nervi toracici, lombari e sacrali emergono al di sotto.
Le dimensioni delle ***radici posteriori*** sensitive sono massime a C8 e S1, che presentano una superficie di sezione di 4-5mm^2, mentre diminuiscono progressivamente fino a raggiungere il minimo nella regione toracica ove le radici posteriori sono più sottili, con una superficie di sezione di 1mm^2, e quindi sono più sensibili al blocco nervoso.
Nella regione lombare ***le articolazioni zigo-apofisarie*** sono orientate su di un piano verticale, rendendo così impossibile la rotazione di una vertebra sull'altra. Nella regione toracica invece le faccette si articolano su di un piano orizzontale e ciò permette la rotazione: anche questo contribuisce a rendere più difficoltosa la puntura a livello toracico.
L'irrorazione arteriosa del midollo è assicurata per il terzo posteriore da 2 arterie spinali posteriori, che sono alimentate molto generosamente, ricevendo da 25 a 40 tributarie radicolari ben sviluppate, mentre i 2/3 anteriori sono irrorati da una sola arteria spinale anteriore, alimentata solo da poche arterie. La più grossa di queste è l'arteria radicularis magna di Adamkiewicz, che alimenta l'arteria spinale anteriore nella zona del rigonfiamento midollare lombare. Essa di solito entra attraverso un singolo forame intervertebrale, in genere sito a sinistra, fra i forami T8 e L3.
La scarsità di anastomosi verticali ed orizzontali con le arterie spinali posteriori giustifica la maggiore fragilità dell'irrorazione anteriore del midollo che è massima in corrispondenza di T4, zona meno vascolarizzata del midollo e più sensibile a danni chimici o fisici, in grado di determinare un'ischemia dell'arteria spinale anteriore che si manifesta con deficit motori a sensibilità conservata. È anche vero che il danno principale è dato dalla formazione di un ematoma di dimensioni tali da sviluppare una pressione nello spazio epidurale di almeno 40 o più mmHg, che rappresenta la pressione arteriosa media di perfusione del midollo toracico.
I punti di repere anatomici per l'esecuzione di una peridurale toracica e per individuare il livello metamerico della procedura sono i seguenti:

- **Apofisi spinosa di C7 o apofisi prominente**
- **Linea orizzontale che unisce le spine delle scapole: interseca l'apofisi spinosa di T3**
- **Linea orizzontale che unisce gli apici inferiori delle scapole: interseca l'apofisi spinosa di T7**

Noi in genere sovrastimiamo la nostra capacità di pungere correttamente proprio lo spazio che ci prefiggiamo di bloccare. A tal riguardo ricordo lo studio di Lirk (3) su cadaveri nel quale si conclude che gli interspazi tra T8 e L4 sono individuati più correttamente di quelli tra C3 e T5 e che il 94% delle punture viene eseguita ad almeno un interspazio più in alto del livello prescelto.

CONSIDERAZIONI FISIOLOGICHE E CONSEGUENZE SULLA PROCEDURA

Le pressioni toraciche e addominali, che variano con i movimenti respiratori e la posizione del soggetto, influenzano direttamente la pressione peridurale.

La pressione endopleurica media misura –7cmH_2O (da –5 a –10cm H_2O) e Usubiaga ha registrato, nel momento in cui la punta dell'ago entra nello spazio epidurale (4), pressioni epidurali toraciche da –3fino a –10 cmH_2O, con una media di -6 cmH_2O.

La negatività della pressione epidurale è particolarmente evidente nella regione toracica media e dipende dalla trasmissione allo spazio epidurale della pressione negativa endopleurica, attraverso le vene epidurali, ma soprattutto, attraverso i forami di coniugazione intervertebrali e lo spazio paravertebrale: essa aumenta a paziente seduto, con i muscoli addominali rilassati.

La comunicazione tra questi spazi e lo spazio peridurale è stata dimostrata con l'iniezione di mezzo di contrasto.

Poiché la massima negatività della pressione epidurale si osserva durante l'inspirazione è opportuno, quando si utilizza, come nella nostra esperienza ***la tecnica della goccia pendente*** di Gutierrez (5), che l'avanzamento dell'ago avvenga specialmente durante gli atti inspiratori. Gli aghi con alette sono ideali per tale tecnica, dato che l'impugnatura dell'ago deve essere ben distante dal punto in cui esce la goccia. La goccia pendente non è controllabile da parte dell'anestesista: essa è segno evidente solo dopo la penetrazione nello spazio epidurale, mentre rileva più tenuamente l'aumento della resistenza al contatto con il legamento giallo e la relativa perdita al suo attraversamento.

Non utilizziamo in genere ***la tecnica della perdita di resistenza***, sia con il mandrino liquido che gassoso, che usiamo per la regione lombare (6): in tale regione la pressione peridurale è debolmente negativa ed è determinata principalmente dallo spostamento della dura verso l'interno, durante l'avanzamento dell'ago, e poco dall'inspirazione. La negatività scompare in tutti i pazienti nella regione sacrale. La tecnica, basata su perdita di resistenza, è quindi più affidabile nella regione lombare e sacrale, ove è poco opportuno utilizzare la tecnica della goccia pendente.

Se nella regione toracica media l'ago viene inserito con direzione obliqua è meno probabile che la dura venga distesa, come a livello lombare ove è inserito quasi perpendicolarmente, e quindi a tale livello la pressione negativa epidurale è poco influenzata dallo spostamento della dura, indotto dall'ago.

Considerata la sottigliezza dello spazio epidurale nella regione mediotoracica, la tecnica della goccia pendente è senz'altro più raccomandabile.

Tuttavia nei pazienti anziani, con bassa compliance dello spazio epidurale e con pneumopatie che aumentano la pressione media endopleurica fino a positivizzarla, prolungando anche la fase espiratoria, la pressione negativa epidurale toracica può ridursi per cui in tal caso può essere opportuno il metodo della perdita di resistenza.

In tal caso non sembra esserci differenza tra mandrino liquido e gassoso sull'incidenza di puntura durale (7).

E' opportuno applicare una pressione intermittente sul pistone della siringa quando si utilizza l'approccio paramediano: essa consente un migliore apprezzamento tattile della perdita di resistenza, per la più alta compliance e la più bassa pressione di apertura del muscolo paraspinoso, laddove una pressione costante sul pistone supera la pressione di apertura del muscolo paraspinoso e mima la perdita di resistenza. Dal colpetto intermittente sul pistone si può meglio distinguere la compliance tissutale e la differenza tra apertura del muscolo e apertura dello spazio epidurale.

Se usiamo la perdita di resistenza con approccio mediano è opportuna invece una pressione costante sul pistone per la bassa compliance e l'alta pressione di apertura del legamento interspinoso.

La sensazione tattile ed il click di passaggio attraverso il legamento giallo, qualunque sia la tecnica usata, non sempre è un indicatore efficace della penetrazione dell'ago nello spazio epidurale toracico. Essa può essere utilizzata come segno di minore importanza per valutare la correttezza della procedura: questo è un elemento che aumenta il rischio di potenziale danno del midollo (8).

La facilità di ***inserzione del catetere*** è un segno importante di approdo allo spazio epidurale. Un eventuale ostacolo al passaggio è indicativo di una malposizione del catetere. La ristrettezza dei forami intervertebrali a livello medio toracico di solito non consente la dislocazione del catetere nello spazio paravertebrale. Inserzioni del catetere nello spazio epidurale superiori ai 5cm possono favorire percorsi aberranti. D'altra parte è opportuno inserire il catetere tra i 3 e i 4cm, perché talora con una distanza inferiore a 3cm sono maggiori i rischi di dislocazione. Questo corrisponde abitualmente, in un soggetto di corporatura normale, ad una lunghezza di circa 10cm a partire dal punto di penetrazione cutanea fino all'estremità distale del catetere.
Un recente studio di autori coreani (9) ha controllato radiologicamente la posizione del catetere epidurale, introdotto tramite un ago di Tuohy inserito nell'interspazio T6-T7 in 106 pazienti, e valutato i risultati ottenuti a seconda che l'ugello sia rivolto in alto o in basso e quindi il catetere indirizzato cranialmente o caudalmente.
I risultati non sono stati molto confortanti: nel gruppo cefalico il 63% dei cateteri è correttamente indirizzato e posizionato, nel gruppo caudale solo il 22% dei cateteri è avanzato e posizionato correttamente. Nel 17,6% dei casi si è visto l'arrotolamento del catetere.

LA PROCEDURA

L'approccio allo spazio peridurale toracico può essere paramediano o mediano. C'è scarsa evidenza in grado di stabilire se l'outcome è realmente diverso con una tecnica o l'altra. Ogni approccio ha i suoi estimatori ed i suoi detrattori. Sono pochi i dati per definire la superiorità di una tecnica all'altra e come recita la regola sacra dell'anestesia: meglio usare la tecnica in cui si è più esperti.
Idealmente la penetrazione nello spazio peridurale dovrebbe essere rigorosamente mediana, qualunque sia l'approccio mediano o paravertebrale. Infatti la penetrazione laterale dello spazio aumenta i rischi di puntura della dura madre, di un vaso o di una radice. Questo ancor più a livello mediotoracico ove lo spazio epidurale è più stretto lateralmente.
Molti autori ritengono preferibile ***l'approccio paramediano*** per un cateterismo mediotoracico sia per l'inclinazione caudale dei processi spinosi che per la ristrettezza della semiluna interlaminare. Tale approccio consente di pungere il legamento giallo ad un angolo più acuto e di evitare del tutto le frequenti calcificazioni e cisti del legamento interspinoso. Il maggiore inconveniente è che la gran parte degli anestesisti non pratica tale accesso a livello lombare e quindi è ancora meno propensa ad usarlo più in alto. Per l'approccio paraspinoso è preferibile usare un ago di Crawford di calibro sottile 18G: l'angolo col quale si inserisce l'ago permette una più agevole introduzione del catetere se si adopera un ago di Crawford a punta retta che un Tuohy a punta angolata di Huber.
La via di accesso consente di eludere l'angolo acuto dei processi spinosi e dei legamenti sopra e interspinosi. L'anestesia locale a ventaglio, che permette di verificare la profondità della lamina, è fatta circa 1,5cm lateralmente alla punta caudale del processo spinoso dello spazio prescelto. Si inserisce l'ago epidurale a lato del processo con un'angolazione di 15° rispetto al piano sagittale e di 55-60° rispetto al piano cutaneo lungo l'asse della colonna.
Noi, che nasciamo come periduralisti lombari, preferiamo l'***accesso mediano*** con il paziente, leggermente sedato, in posizione seduta, inclinata leggermente in avanti, con il collo flesso e le braccia incrociate, aiutato da un infermiere, a meno che non vi siano motivi clinici tali da imporre la posizione laterale. La posizione seduta ci consente di sfruttare al massimo in inspirio la negativa pressione endopleurica ed epidurale col metodo della goccia pendente.
Se l'ago è inserito sulla linea mediana può urtare contro il processo spinoso anche se l'ostacolo più comune è la lamina vertebrale, inclinata posteriormente e verso il basso. L'angolo di puntura è in genere calcolato durante l'infiltrazione dei piani superficiali con un ago di 3cm.
L'ago epidurale è introdotto con un angolo di circa 30-40° ad una profondità di circa 2,5cm, fino a che non è fissato nel legamento interspinoso. A questo punto viene rimosso il mandrino e viene posta una goccia di soluzione fisiologica o di anestetico locale nella calotta dell'ago, che viene fatto avanzare verso il legamento giallo. Il pollice e l'indice di entrambe le mani assicurano per le alette l'ago che avanza millimetro per millimetro, con le altre dita che esercitano una funzione di freno sulla schiena del paziente. Gli occhi dell'operatore sono fissi sulla goccia pendente. Quando viene

raggiunto lo spazio epidurale la goccia è risucchiata verso l'interno con maggiore forza aspirativa se si invita il paziente ad una profonda inspirazione; viene anche avvertita la perdita di resistenza anche se di meno rispetto alla tecnica del mandrino.

EFFETTI DEL BLOCCO

È possibile titrare il livello del blocco, limitandolo ad un numero ristretto di metameri, tenendo presente che per bloccare un segmento sono necessari 0,5-0,8ml di soluzione anestetica. Questo consente di effettuare blocchi paucisegmentali con scarso impatto sull'emodinamica del paziente per la minore simpaticolisi.

Al di sotto di T4 un blocco esteso provoca una simpaticolisi periferica con vasodilatazione a livello addominale, se sono bloccate le fibre splancniche, e della pelvi e degli arti inferiori. I soggetti sani in posizione supina compensano la riduzione della pressione arteriosa media con vasocostrizione efferente simpatica al disopra del blocco, a carico della testa, del collo e degli arti superiori. Essa è mediata, tramite i barocettori, dai nervi simpatici vasocostrittori cervicali da T1 a T5, e dalle catecolamine della midollare del surrene, in quanto il blocco splancnico non è quasi mai totale.

Le arteriole maggiori rispondono prevalentemente agli stimoli nervosi, mentre le piccole arteriole e le venule rispondono prevalentemente alle catecolamine circolanti.

Infine la capacità di autoregolazione degli sfinteri precapillari si sviluppa poco tempo dopo la cessazione dell'attività nervosa e ciò contribuisce al recupero del tono vascolare ed al compenso.

I due stimoli simpatici (nervoso e ormonale) determinano un aumento della contrattilità e della frequenza cardiaca in media del 22% con aumento medio della gittata cardiaca del 21%.

L'idratazione pre-blocco, insieme con i meccanismi di compenso, dianzi citati, permette il mantenimento della pressione arteriosa media a livelli vicini alla norma, sempre che il blocco non superi T4.

Al di sopra di T4 si parla di ***Epidurale Toracica Alta (HTEA)*** che determina i seguenti effetti: blocco dei riflessi cardiaci segmentali nei segmenti T1-T4, blocco delle efferenze dal centro vasomotorio, blocco dei nervi vasocostrittori del capo, del collo e degli arti superiori.

Se il blocco è esteso e va da T1 a L4 si sommeranno a questi gli effetti sopra descritti per il blocco esteso sotto T4.

Nei blocchi paucisegmentali in soggetti sani le alterazioni associate della pressione arteriosa media si sono rivelate sorprendentemente modeste. Poiché la HTEA si pratica quasi sempre in cardiochirurgia è opportuno valutarne gli effetti nei pazienti cardiopatici che si devono sottoporre ad intervento e specialmente nei coronaropatici.

I pazienti coronaropatici non rispondono allo stimolo simpatico con la normale dilatazione coronarica, bensì con una costrizione con conseguente rischio di aritmie e di infarto. Dati sperimentali dimostrano che in cani con legatura delle coronarie una HTEA riduce la frequenza di aritmie e di necrosi miocardica (10). In tali pazienti la HTEA migliora la funzione ventricolare sn e riduce gli episodi di ischemia intra e post-operatoria durante interventi di rivascolarizzazione miocardica (11). Inoltre l'epidurale riduce la ipercoagulabilità di questi pazienti riducendo i livelli plasmatici dell'inibitore 1 dell'attivatore del plasminogeno (12).

La migliore funzione ventricolare dipende soprattutto da una maggiore efficienza della fase diastolica (13).Gli effetti benefici dell'epidurale toracica alta dipendono da un aumento del flusso coronarico transmurale e da una riduzione della richiesta di O_2, che non solo riducono le aree ischemiche ed i livelli post-operatori di troponina, ma migliorano la funzione ventricolare regionale e globale (14).Sono altresì ridotte le aritmie post-operatorie (15).

A livello respiratorio il blocco epidurale toracico oltre alle afferenze sensitive può interessare le efferenze motorie con paralisi dei muscoli intercostali e addominali ma non del diaframma, in quanto il rischio di un blocco del nervo frenico (C3-C5) è estremamente basso. Le modeste riduzioni della performance ventilatoria, dovuta al blocco, sono ampiamente compensate dall'efficace analgesia che consente una più precoce estubazione, una maggiore aderenza al programma fisioterapico, un miglioramento della CV, della CFR, della PaO_2 ed una più efficiente espettorazione.

ATTUALITA'

Recenti esperienze con studi prospettici randomizzati (16) e metanalisi (17) hanno dimostrato i vantaggi dell'epidurale toracica combinata all'anestesia generale rispetto all'anestesia generale da sola.

Nell'Ottobre di quest'anno sono stati pubblicati sul J Cardiothoracic Vascular Anesthesia due lavori interessanti relativi all'epidurale toracica.

Il primo lavoro, che si propone di definire l'eterno interrogativo sulla migliore posizione del paziente per eseguire la procedura, è di autori giapponesi (18) che hanno, con uno studio prospettico e randomizzato eseguito su 41 pazienti, sottoposti a intervento di rivascolarizzazione miocardica, messo a confronto la posizione seduta e la posizione laterale.

I risultati sono stati i seguenti: la percentuale di successi è sovrapponibile, i tempi di inserzione del catetere nel gruppo seduto sono significativamente più brevi rispetto al gruppo in posizione laterale, l'accuratezza di raggiungere lo spazio previsto al primo tentativo è stata del 93% nel gruppo seduto e del 73% nel gruppo in laterale, senza differenza statisticamente significativa, nel gruppo seduto il 20% dei pazienti ha presentato un riflesso vagale con ipotensione e bradicardia con differenza significativa rispetto al gruppo in posizione laterale.

Questa posizione quindi si fa preferire nei pazienti cardiopatici in cui uno stimolo vagale può precipitare una situazione di compenso emodinamico labile o nei pazienti con turbe severe della conduzione in grado di evolvere, per stimolo vagale, verso gradi sempre più rischiosi di BSA o BAV.

Il secondo studio pubblicato sulla stessa rivista è di autori statunitensi (19). E' uno studio epidemiologico sulla metodologia didattica utilizzata per l'apprendimento della procedura da parte dei giovani anestesisti in USA. I risultati sono molto interessanti e sono ottenuti da una review retrospettiva di 2007 epidurali: il 34% dei centri posiziona più frequentemente cateteri peridurali toracici che lombari, il 92% dei centri utilizza il cateterismo peridurale prevalentemente per l'analgesia post-operatoria e l'88% dei centri insegna la procedura lombare prima di passare alla toracica, mentre il restante 12% fa viceversa. Preferiscono l'approccio mediano a quello paravertebrale anche a livello toracico gli anestesisti che acquisiscono la loro iniziale esperienza sul campo a livello lombare.

La seconda parte dello studio è una survey su di un programma accreditato dall'America Board of Anesthesiology: 60 residenti sono stati divisi a random in 2 gruppi: il primo ha imparato prima la tecnica lombare e poi quella toracica, il secondo ha svolto un programma didattico opposto. Non sono risultate tra i 2 gruppi differenze significative dal punto di vista statistico sia per quanto attiene il grado di difficoltà tecnica della procedura sia per l'incidenza di complicazioni ad essa correlate.

Nel 2006 il sito della Society of Cardiovascular Anesthesiologists ha pubblicato un pro e contro sul tema "Conscious Neuraxial Anesthesia is a Viable Alternative to General Anesthesia in Cardiac Surgery?".

La voce pro (20) raccomanda l'HTEA a paziente sveglio per la chirurgia cardiaca a cuore battente specie per le recenti tecniche mini-invasive cardiochirurgiche, sottolineando i vantaggi sul circolo coronarico e sulla funzione miocardica dianzi descritti. Raccomanda l'associazione di anestetici locali ed oppioidi che consente di evitare la somministrazione pre e intra-operatoria di forti dosi di sedativi, che potrebbero deprimere la funzione ventilatoria dei pazienti. In questi la sedazione sarà garantita anche dal riassorbimento dell'oppiaceo epidurale. Si enfatizza la necessità di una accurata selezione dei pazienti: sono arruolabili soprattutto i pazienti con stenosi della discendente anteriore sinistra e/o della coronaria destra, facilmente accessibili per il chirurgo, mentre la rivascolarizzazione dell'arteria circonflessa sinistra richiede la posizione di Trendelenburg e la lussazione del cuore, di non facile performabilità a paziente sveglio.

Da escludere anche i pazienti con notevole compromissione della funzione di pompa, in cui una residua forma di compenso è sostenuta dal tono simpatico. Notevoli sono i vantaggi legati alla

tecnica fast tracking per la più precoce estubazione, la migliore gestione del dolore post-operatorio, la minore degenza in ICU e in ospedale. Si avvantaggiano in modo particolare i pazienti coronaropatici con COPD (21) che potrebbero avere difficoltà nel weaning postoperatorio e i pazienti con stenosi carotidee severe, con compromesse funzioni cerebrovascolari in cui il monitoraggio verbale intra-operatorio a paziente sveglio, può risultare di particolare utilità (22).
Naturalmente ancora più vincolanti sono le controindicazioni all'epidurale in genere, specie per situazioni cliniche a rischio di ematoma (Tempo di Tromboplastina < 80%, Tempo di Protrombina > 40sec, Piastrine < 100.000/ml e uso di farmaci antiaggreganti negli ultimi 10 giorni). Con queste accortezze è minimo il rischio di ematoma in corso di HTEA: su 10.000 procedure è riportato 1 solo caso di un giovane paziente, sottoposto a sostituzione valvolare aortica, in cui l'ematoma si è sviluppato nel post-operatorio dopo uso di un farmaco trombolitico, l'alteplase, per flushare un catetere venoso centrale ostruito (23). Un'immediata laminectomia ed evacuazione dell'ematoma hanno consentito il completo recupero neurologico del paziente.
L'editoriale contro (24) insiste sui rischi di ematoma epidurale, particolarmente pericoloso se legato al cateterismo e se sopraggiunto durante o dopo l'intervento cardiochirurgico, a causa delle difficoltà tecniche legate alla necessità di un reintervento neurochirurgico in un paziente operato di rivascolarizzazione e obbligato ad un trattamento ipo o anticoagulante. Si discute sull'opportunità di ritirare il catetere epidurale una volta assicurato un buon assetto coagulativo. Per ridurre tali rischi si enfatizza la scelta di posizionare il catetere il giorno precedente l'intervento e comunque almeno 1 ora prima della eparinizzazione. Viene evidenziata la casistica di Karagoz (21) con un 3% di fallimento nella inserzione del catetere e come più tentativi aumentino i rischi di ematoma.
Altro elemento negativo è legato al fatto che il respiro spontaneo del paziente può interferire con la chirurgia e che la frequenza di comparsa di un pneumotorace in cardiochirurgia oscilla tra il 10 e il 28% portando in alcuni casi ad una insufficienza respiratoria che richiede l'intubazione e quindi l'anestesia generale del paziente. D'altra parte, anche se rara, è possibile per livelli di HTEA superiori a C5, come quando è necessario portare il livello anestetico cutaneo fino al giugulo, avere una paralisi diaframmatica che impone l'assistenza ventilatoria meccanica, previa intubazione.
Altri motivi per la conversione di una HTEA in una GA (General Anaesthesia) sono una tosse ostinata del paziente e una importante instabilità emodinamica per emorragia intraoperatoria.
In alcuni pazienti la necessità di un prelievo della vena safena impone un blocco midollare lombare con incremento ulteriore dei rischi di tossicità da anestetico locale, di complicanze midollari e di instabilità cardiovascolare (25).
Molti pazienti richiedono una forte sedazione che può precipitare una insufficienza respiratoria, già favorita da una eventuale paralisi dei muscoli intercostali. Lo stato di ansia, comune a tutti i pazienti che si devono sottoporre a chirurgia, ancor più se delicata e complessa, è acuito dal fatto di dover stare immobili con il torace aperto per alcune ore. Uno stato di ansia elevato, indesiderabile in un coronaropatico, può indurre al passaggio ad una GA.

LA NOSTRA ESPERIENZA

Noi abbiamo utilizzato l'anestesia epidurale mediotoracica in un protocollo di anestesia integrata per interventi di chirurgia toracica, posizionando il catetere al tavolo operatorio il giorno dell'intervento con un onset medio di circa 30 minuti prima dell'inizio della chirurgia.

MATERIALI E METODI

La nostra casistica riguarda 60 pazienti, arruolati da Febbraio 2004 ad Ottobre 2006, previo consenso informato e in base ad una chek list di inclusione ed esclusione.
Il case mix chirurgico è costituito da 4 pneumonectomie, 5 lobectomie con costectomie e 51 lobectomie.
La divisione per sesso vede la notevole prevalenza di maschi (*52*) sulle femmine (*8*).
La tipologia dei pazienti dal punto di vista del rischio anestesiologico è in media di classe 3 ASA.
Sono presenti nella casistica pazienti molto immunodepressi (leucemia), pazienti con importanti patologie cardiache
(recente IMA, pazienti con recente rivascolarizzazione miocardica) e vascolari (stenosi carotidea

del 55%, pazienti operati di by-pass aorto-bifemorale), pazienti con insufficienza respiratoria importante con riduzione del FEV1 al disotto del 65%.
L'accesso utilizzato è stato sempre quello mediano (nasciamo come periduralisti lombari) ed è sempre stato coronato da successo nel corretto posizionamento del catetere peridurale, fatto proseguire per almeno 3cm nello spazio.
La posizione del paziente è sempre stata seduta ed è stato utilizzato ago di Thuoy 18G. La puntura è avvenuta per via mediana, inclinando l'ago da 25°a 40° sul piano cutaneo e pungendo a livello di T6-T7. Il metodo per ricercare lo spazio peridurale è stato quello della goccia pendente.
La ventilazione monopolmonare dei pazienti anestetizzati è sempre stata assicurata con posizionamento di tubo di Carlens o di White.
I pazienti sono stati premedicati in reparto con Midazolam 0,07mg.kg^{-1} per via intramuscolare almeno 1 ora prima dell'inizio dell'intervento. In sala operatoria, dopo aver assicurato un adeguato accesso venoso periferico e arterioso radiale per l'IBP, abbiamo potenziato la premedicazione con somministrazione endovenosa di Sufentanil 0,21mcg.Kg^{-1} e Atropina 0.007mg.kg^{-1}. L'induzione è stata effettuata con bolo di Propofol 1,7mg.kg^{-1} e la miorisoluzione ottenuta con Cisatracurium 0,17mg.kg^{-1}. Il mantenimento è stato assicurato da inalazione di miscela di O_2 e Aria al 50% con aggiunta di vapori di Sevorane intorno all'1% e, se necessari, altri boli di Cisatracurium a dosi dimezzate.
La decurarizzazione è stata praticata sempre con Atropina 0,014mg.kg^{-1} e Prostigmina 0,028mg.kg^{-1}.
Da Febbraio 2004 a Novembre 2005 è stato usato come anestetico locale la Ropivacaina con la quale sono stati eseguiti 38 interventi (***gruppo R***: 35 M e 3 F), dal Dicembre 2005 ad Ottobre 2006 sono stati eseguiti 22 interventi (***gruppo L***: 17 M e 5 F) usando la Levobupivacaina, che ha sostituito la prima molecola nel nostro prontuario.
I protocolli farmacologici ed i dosaggi dell'anestetico locale e dell'oppioide sono stati i seguenti:
Gruppo R: *protocollo intra-operatorio*: bolo, diviso tra dose test di 5ml attraverso l'ago e di altri 5ml, dopo il posizionamento del catetere, di Ropivacaina 50mg allo 0,5% associata a Sufentanil 1mcg per ml, seguito dopo 10 minuti da altro bolo di 5ml di Ropivacaina 25mg allo 0,5% in 5ml associata a Sufentanil 1mcg per ml.
Quando l'intervento si è prolungato oltre i 150 minuti sono stati somministrati boli supplementari di 5ml di 25mg di Ropivacaina allo 0,5% e Sufentanil 1mcg per ml ogni 60 minuti.
Protocollo post-operatorio: infusione continua per le prime 48 ore ,con il paziente in TIPO. di miscela di Ropivacaina 0,2% (2mg/ml) e Sufentanil 0,5–1mcg per ml in pompa elastomerica alla velocità di 5ml/ora; nelle 48 ore successive, con il paziente in reparto, anestetico locale alla stessa concentrazione con Clonidina alla dose di 0,625 mcg per ml sempre alla stessa velocità di infusione.
Gruppo L: *protocollo intra-operatorio*: bolo, dopo dose test di 5ml attraverso l'ago di altri 5ml, dopo il posizionamento del catetere, di Levo allo 0,37% 37mg e Sufentanil 1mcg per ml, seguito dopo 10 minuti da altro bolo di 5ml di Levo allo 0,37%, pari a 18,5mg e Sufentanil 1mcg per ml.
Quando gli interventi si sono prolungati oltre i 180 minuti sono stati somministrati boli supplementari di Levo 18,5mg in 5ml allo 0,37% e Sufentanil 1mcg per ml ogni 60 minuti.
Protocollo post-operatorio: infusione continua per le prime 48 ore, con il paziente in TIPO, di Levobupivacaina 0,125% e Sufentanil 0,5–1mcg per ml in pompa elastomerica alla velocità di 5ml/ora; nelle 48 ore successive, con il paziente in reparto, anestetico locale alla stessa concentrazione con Clonidina alla dose di 0,625mcg per ml sempre alla stessa velocità di infusione.
RISULTATI
I pazienti si sono tutti risvegliati al tavolo operatorio, senza agitazione e dolore di rilievo e sono stati trasferiti in TIPO.
Intra-operatoriamente si è registrata una eccellente stabilità cardiovascolare tranne in 1 paziente del gruppo R, che ha presentato un episodio di bradicardia ed ipotensione, risolto con incremento del riempimento volemico e dosi refratte di Efedrina, e 4 pazienti sempre del gruppo R, che hanno presentato solo bradicardia, senza ipotensione, risolta con la somministrazione di dosi refratte di

Atropina.
Nel post-operatorio solo un paziente del gruppo R ha presentato globo vescicale in seconda giornata.
Tutti i pazienti dei 2 gruppi hanno tenuto i cateteri in situ per i 4 giorni post-operatori programmati, tranne:
2 rimozioni del catetere dopo 24 ore per dislocazione dello stesso, 4 pazienti che hanno richiesto una rimozione dopo 6 giorni per consentire un ulteriore pain relief per un programma di fisioterapia respiratoria, 1 paziente che ha tenuto in situ il catetere per 14 giorni a causa della necessità di un reintervento.
Non è mai stata riscontrata infezione a livello del sito di inserzione né nausea e /o vomito e/o prurito.
Per quanto attiene il dolore post-operatorio tutti i pazienti sono stati monitorati nelle 96 ore a intervalli di 3 ore per le prime 24 ore e di 6 ore per le successiva 24 ore, trascorse in TIPO, e di 12 ore per le 48 ore, trascorse in reparto.
I risultati sono stati i seguenti:

- 43 pz VAS medio a riposo < 1 e VAS medio in movimento < 2.
- 17 pz VAS medio a riposo > 2 e VAS medio in movimento < 3.

In quasi tutti i pazienti è comparso nelle prime ore del post-operatorio dolore alla spalla dal lato operato, risolto con 30mg di Ketorolac, somministrato per via endovenosa. La patogenesi del dolore è legata fondamentalmente alla postura laterale del paziente che deve stare per ore con l'arto superiore flesso al gomito ed abdotto, al fatto che talora la cupola pleurica sfugge al blocco, perché la chirurgia interessa i lobi inferiori ed all'irritazione della pleura diaframmatica.
Non è stata riscontrata nessuna riduzione della motilità, valutata con scala di Bromage modificata.

CONCLUSIONI

Dalla nostra esperienza e dai dati della letteratura si può senz'altro concludere che l'anestesia epidurale medio-toracica rappresenta in pazienti selezionati da sottoporre ad interventi di chirurgia toracica un golden standard sia nell'ambito di un protocollo di anestesia integrata che per il trattamento del dolore post-operatorio.
Questo per la notevole stabilità emodinamica intra-operatoria, per la riduzione del dosaggio complessivo medio dei farmaci, usati per l'anestesia generale, per il notevole pain relief post-operatorio, per il più precoce svezzamento dalla ventilazione meccanica, per la migliore compliance al nursing ed alla fisioterapia respiratoria, per la più precoce mobilizzazione, i minori rischi di eventi trombo-embolici, per la minore durata di degenza in TIPO ed in reparto ed infine per il notevole abbattimento dei costi.
L'anestesia epidurale toracica alta, utilizzata quasi esclusivamente in cardiochirurgia, a paziente sveglio negli interventi a cuore battente ed in altri casi in un protocollo di anestesia integrata, si va sempre più diffondendo, per gli innegabili vantaggi sul circolo coronarico e sul lavoro cardiaco, ma restano ancora forti perplessità per i rischi di ematoma, difficile da trattare in un post-operatorio che impone un trattamento anticoagulante efficace. Di qui la necessità di definire nel modo migliore il target di pazienti che per il profilo psicologico, per il quadro clinico, per l'indicazione chirurgica e per l'assetto coagulativo, ottiene il meglio dal rapporto rischi/benefici, con notevole prevalenza del denominatore e scarsa incidenza del numeratore.

SPINAL CORD STIMULATION IN CHRONIC PAIN CONTROL

F.Ferraro, MD

II° **Dipartimento di Scienze Anestesiologiche, Chirurgiche e dell'Emergenza**
Università degli Studi di Napoli

Epidural spinal cord stimulation (SCS) was born in the end of Sixties as reversible and non-destructive method to treat chronic pain. Now SCS is an established treatment for intractable neuropathic pain. SCS is performed using an implantable pulse generator connected to leads with electrodes positioned in the dorsal epidural space. The electrical stimulation of the ascending and descending dorsal column fibres, achieves paresthesia covering the area of pain and so it inhibits pain transmission. It is based on the Gate Control Theory, introduced by Melzack and Wall in 1965. The new SCS system based on cardiac pacemaker technology is totally implantable and with percutaneous method[1](fig.1). More recent studies indicate that SCS releases substance P serotonin, noradrenaline and GABA in the dorsal horns; activation of the GABAB receptor may be linked to a decrease in the release of glutamate and other excitatory amino acids, resulting in a decrease of neuropathic pain. The progressive technology and methodology evolution of the last years have spread the technique with improving results and the acquisition of new indications[2, 3]. Today the clinical indications for SCS are mainly peripheral vascular diseases (PVD)[4],refractory angina[5], failed back surgery syndrome (FBSS)[6,7] spasticity, complex regional pain syndrome (CRPS) type 1 and type 2, spinal cord stenosis and neuropathic pain[8, 9]. In addition, spinal cord stimulation suppresses visceral response to colon distension in an animal model and case series in the literature report an effective outcome of SCS on intractable visceral pain [10, 11]. SCS is one of the most effective modalities for management of refractory neuropathic pain unresponsive to conservative therapies and in our experiece we have treated with SCS (Medtronic Itrel3/Pisces Quad SCS System)(fig.2) 21 patients (pts.) (14M, 7F) of age between 47 and 80 (63±14)(mean ± SD). Patient's diseases were peripheral vascular disease (PVD) (15 pts.), peripheral neuropathy (PN) (3 pts.), deafferentation syndrome (DS) (2 pts.), causalgic syndrome (CS) (pts.1); for 7 patients indication was pain control, pain control and peripheral revascolarization for other 14. Access sites were T10-T11 (1 pts.), T11-T12 (1 pts.),T12-L1(3 pts.), L1-L2 (9 pts.), L2-L3 (7 pts.) level. The stimulation parameters were pulse width 210 µ sec., amplitude 2.3mA, frequency of 80 Hz, and between 0,8 and 8 volt (min 2,4±1,3 volt; max 6,4±1,5 volt). Mode of stimulation was continuous for the first month after internalization of SCS, then automatic on/off cycling mode (30 min on - 15 min off). For pain evaluation we use visual analogical scale (VAS) (0 no pain; 10 unbearable pain). Only 15 of 21 patients (66,67%) after time test (fig.1) between 13 and 57 days (30±18) received internalization of SCS (fig.2); this emphasizes the importance of screening

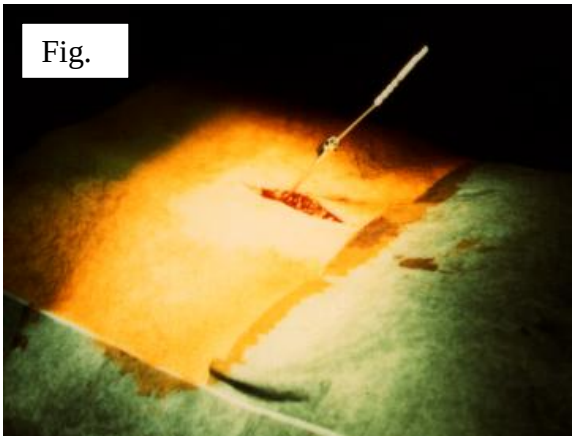

Fig.

Fig.2

before permanent implantation. 2pts. (10,5%) were out from the study (failed for no collaboration) and received only pharmacological epidural therapy. In patients with internal SCS, VAS was reduced from 7,8±1,3 to 1,8±2,3, with 75,68%±30,56 reduction of pain. Besides in one patient, during time test we relieved a sterile inflammatory reaction to implanted material in subcutaneous tract of percutaneous extension of electrode, treated with SCS removal[12]; two patients were dead for other pathology. Our experience with percutaneous placement, relieving satisfactory results, agrees with the reported outcome results found in the international literature. We can reduce drug administration in the pain management with SCS. Besides the percutaneous technique reduces discomforts on the contrary of the minimal laminectomy technique, more destructive and all that allows a life quality improvement in these patients.

SCS has proven to be an effective however an invasive and relatively expensive treatment. On the other hand this technique has proven to be cost effective in the long term despite its high initial cost and the new puncture trial method is less invasive and can reduce psychological resistance of the patient for SCS manipulation[13]. Finally the SCS has been successful in providing analgesia, improving function, and enhancing quality of life for patients suffering from intractable chronic pain conditions[14, 15].

EMOTIONAL AND PHYSICAL PAIN IN WOMEN WITH NEUROLOGICAL PAIN RELATED CONDITIONS: HEADACHE, FYBROMIALGIA AND RLS.

Silvestri R., Aricò I
Sleep Medicine Center, Messina Medical School Italy

Despite a significant inherent resilience, women are more affected by health conditions involving physical as well as psychological pain. Depression as an emotional burden is definitely more prevalent in females contributing to lower central pain threshold via specific neuromodulatory alterations. Gender related differences in the perception/experience of pain may be related to different brain connectivity(increased in females), thresholds, modulatory systems, genetic and hormonal influences. Three major clinical pain related conditions best exemplify gender effects over prevalence and symptoms characteristics.

Fybromialgia (FM) is a central pain disorder with a 2:1=F:M ratio, characterized by chronic widespread pain due to excessive central sensitization. It relies on an increased aberrant response of the dorsal horn neurons to painful stimuli leading to allodynia, hyperalgesia, fatigue and sleep disruption. BDNF, substance P and glutamate are excessively released whereas there appears to be demodulation of the descending pain pathways (NE, 5 HT). Sleep disturbance and fatigue are core symptoms of FM. Up to 86% of FM patients experience sleep disturbance (Kranzler et al, 2002). They usually report the following types of sleep complaints (Harding SM, 1998): insomnia, non restorative sleep, increased awakenings. Up to 96% of FM patients suffer from fatigue, lacking the strength or energy to function normally. Alpha sleep, typical of FM, consists of alpha intrusions in NREM sleep; alpha-delta patterns with alteration of σ/δ ratio decay across sleep are strongly associated with unrefreshing sleep and severity of symptoms. Also fewer spindles and a decreased power in spindle frequency activity are reported in women with FM and pain, probably due to impaired thalamo-cortical mechanisms.Growth hormone (GH) is reduced in FM as well as melatonin (MLT). Data about an estroprogestinic influence on fybromialgia symptoms are scanty and non conclusive (Okifuji A and Turk D, 2006). Possible therapeutic implications are: behavioural measures, antidepressants, MLT, GH (impracticable), Pregabalin, Gabapentin, Sodium oxybate, anti TNF-α medications. Several trials with amitryptiline (25-50mg) demonstrated a pain threshold increase and sleep consolidating effects but no effect on α/δ sleep. More recently dual reuptake inhibitors (SNaRI) such as duloxetine and venlafaxine have been more in use due to a more favourable profile as far as side effects. Pregabalin is an α2-δ ligand that causes increase of the cellular expression of Ca-channels and a decrease of SP and Na, consolidates nocturnal sleep, by increasing SWS and reduces neuropathic pain. Sodium Oxybate is a GABA-β agonist recently employed in narcolepsy. It increases SWS and decreases α-EEG sleep. Due to a high potential for abuse and increased parasomnias, it does not hold a favourable profile to be recommended for general practice prescriptions.

Migraine is a neurological syndrome characterized by altered bodily perceptions, severe headaches, and nausea, more common in women than in men (F:M=2:1). Migraine strongly relies on female hormonal asset and cyclic changes. Its frequency is usually enhanced during the menstrual/premenstrual period, tends to decrease during pregnancy parallel to progesterone rising values and is most often abated by menopause after a temporary rise in the perimenopausal interval, once estrogens sources are depleted unless hormonal replacement therapy (HRT) is started. Female hormonal effects on migraine are consistent and well known, having been extensively reported. 25% of female patients experience their first migraine attack coincidental with menarch; 60% report worsening of migraine symptoms/frequency before and/or during menses (catamenial migraine) especially in familial cases, whereas only 22% of migraine symptoms start or get worse during menopause. In our Center, we observed a F/M ratio of 3:1.

18% of our sample reports altered sleep quality with females suffering from initial insomnia more than males whereas depression, only in subjects with migraine without aura, is associated with sleep

complaints without gender differences.
According to the International Classification of Sleep Disorder (ICSD2, 2005) and to the standard diagnostic criteria (Allen RP et al, 2003), restless legs syndrome (RLS) is a sleep-related movement disorder characterized by uncomfortable sensations affecting the legs, which begins or worsens at rest, improves or disappears with movement, and occurs or worsens in the evening or at night.
Although the etiopathogenesis of RLS is still unknown, several reports suggest a dopaminergic system dysfunction as the basic mechanism. The neuroanatomical basis of this dysfunction is also unclear, but a hyperexcitability of the spinal locomotor generator, due to an impairment of inhibitory supraspinal descending neurons to the dorsal spinal gray matter, has been postulated (Clemens S et al, 2006).
Several studies report a nearly double prevalence of RLS in females comparable to males (Berger K et al, 2004). Studies have shown that more than a fifth of women have RLS during pregnancy; most of them experience RLS symptoms for the first time and have a remission around the time of delivery (Manconi et al, 2004; Tunç T et al, 2007). In one study (Berger K et al, 2004), pregnancy was found to be a risk factor for RLS at later ages, suggesting that the degree of risk increases with the number of children. Symptoms (11%-27% prevalence) peak in the III° trimester, strongly associated with hormonal asset (Manconi M et al, 2004): increased estrogens, progesterone and prolactine. Infact estrogens are known to exert in the rodent an antidopaminergic effect mediated by alfa estrogen receptors of the medial preoptic area whereas progesterone increases neuronal excitability and is responsible for the physiologic proprioceptive hyperreflexia. As far as prolactine is concerned, since dopamine is known to be the main inhibitor of prolactine hypophisis secretion, a dopamine decrease secondary to prolactine rise could be hypothesized.
In a minority of women first RLS symptoms occur at menopause. Wesström J and colleagues (2008) demonstrated that vasomotor symptoms during the premenopausal period are strongly associated with the presence of RLS as if a decreased ovarian estrogen secretion could alter at the same time neuromodulation and hypothalamic thermoregulation. Also secondary cardiovascular consequences and hypertension prevail in RLS females and are strongly related to the presence of depressive symptoms, in association with a lowered pain threshold. In our Center, a total of 72 (46 F and 26 M, mean age 53.2 and 52.4 yrs, respectively) patients have been diagnosed as RLS during the last 3 years(8.3% of all patients reporting to a tertiary center for sleep medicine). On all patients available data include: anthropometric data (weight, BMI), physical/neurological examination, personal and familial history, including comorbid disorders and treatment, iron status (blood count, Hb, sideremia, ferritin, transferrin). Furthermore results from self administered scales were obtained in all patients: Epworth Sleepiness Scale (ESS), IRLS-RS (Allen et al, 2003), Pittsburg Sleep Quality Index (PSQI), Hamilton Anxiety Rating Scale (HAM-A), Beck Depression Inventory (BDI), Short Form-36 2v Health Survey, (SF-36 2v). No statistical gender related differences were found as far as age, BMI, ESS, IRLS-RS scores, mean age of onset and symptoms duration between men and women. 38.8% of patients suffered from hypertension, 26.3% from dyslipidemia, 25% from migraine, 11.1% from nocturnal eating disorder, 20.8% from tyreopathy, 58.3% from mood/anxiety disorder. Patients with a positive RLS familial history were younger, mainly females, with an earlier mean age of onset compared to sporadic cases. 29 women were menopausal, had a mean parity index 1.8; in 17% of women symptoms started with the first pregnancy and in 17% with menopause.
Different Dopa-agonists were prescribed to all patients with IRLS-RS drastically improving after 1 month, more in men than in women. Significant statistical differences were found for PSQI, BDI and HARS, as more attained in women. Moreover a menopausal symptom onset seems to be associated with a less serious form of the disorder, whereas RLS onset during pregnancy was more related to the presence of hypertension; also an older age of onset and longer duration of symptoms were risk factors for hypertension.
From a Multicenter Italian Study on sleep disorders in peri and postmenopausal women (data not published yet), preliminary results confirm a strong association of hypertension and depression with

RLS, even stronger than seen in patients with obstructive sleep apnea (OSAS).
Women affected by chronic neurological conditions involving constant or recurrent pain, have a disabling compromised quality of life, severely impacting their work ability and social interactions. They are also often stigmatized and are prone to excessive albeit unsuccessful use of sanitary resources. Family and social networks including psychotherapeutic approaches should be considered and encouraged in order to optimize therapeutic holistic strategies.

ADEQUATE DEPTH OF ANAESTHESIA - HOW CAN WE AVOID CONSCIOUS PERCEPTION OF PAIN DURING EXPERIMENTAL SURGERY IN LABORATORY ANIMALS?

K.A. Otto

Hannover Medical School, Central Laboratory Animal Facility, Carl-Neuberg-Str. 1, D-30625 Hannover, Germany
otto.klaus@mh-hannover.de

International and national animal welfare guidelines require that general anaesthesia is maintained at a level sufficient to [1,2]

a) minimize changes in physiologic function
b) block responses to noxious stimulation
c) produce unconsciousness as rapidly as possible in order to avoid conscious perception of pain.

Unconsciousness in animals refers to a state in which stimuli are not perceived.[1] In order to achieve these goals, for example, the use of end-tidal anaesthetic concentrations ranging from 1.25 to 1.50 times the minimum alveolar concentration (MAC) has been suggested for maintenance of general anaesthesia with volatile agents during surgery in laboratory animals while anaesthetic concentrations corresponding to 1.0 MAC may be sufficient to produce unconsciousness during non-surgical anaesthesia.[1] Clinical end-points that have been used to monitor adequacy of anaesthetic depth in man and various animal species include eye reflex responses (e.g. pupil size, eye movement, position of the eyeball) introduced by Guedel almost 90 years ago [3] as well as changes in somatosensory responses, skeletal muscle tone, movement response, respiratory and haemodynamic variables, respectively, [4] during anaesthesia and noxious stimulation.

A questionnaire in human patients [5], however, revealed that

a) the aforementioned clinical signs may be insufficient in order to assure adequate depth of surgical anaesthesia
b) intraoperative awareness may be associated with pain perception but also with analgesia meaning that intraoperative analgesia can be most likely assured by a combination of both unconsciousness and treatment with analgesic drugs.

Consequently, the question arises how can we assess unconsciousness in animals and thereby assure lack of pain perception? Clinical signs recommended as indicators for the onset and presence of unconsciousness in man include

a) loss of movement [4]
b) loss of the eyelash reflex [6, 7]
c) a minimum of 1.3 MAC end-tidal volatile anaesthetic concentration supplemented with an opioid and nitrous oxide [8]
d) the absence of recall of intraoperative events [9, 10]
e) absence of eye opening to command [11]
f) uninhibited release of a hand-held object [7]
g) EEG median frequency of less than 6.8 Hz (propofol anaesthesia, quiescent room, no surgical stimuli) [11] or less than 5 Hz (methohexital) [12].

Many of these indicators, however, are not applicable to animals owing to the lack of verbal communication. Therefore, maintenance of adequate anaesthetic depth may become a major ethical issue in circumstances in which there is a potential that signs of inadequate anaesthesia might be masked. [13] Such circumstances exist in all types of surgeries where the movement response and the skeletal muscular tone are suppressed by neuromuscular blocking drugs (NMBDs).

Moreover, during experimental cardiac surgeries the assurance of adequate depth of surgical anaesthesia may be even more affected due to changes associated with the employement of an cardiopulmonary bypass (CPB). [14] The extracorporal circulation results in an isolation of the lungs from systemic circulation leading to the loss of monitoring volatile end-tidal anaesthetic concentrations (V_{ET}). [15] However, contradiction exists on the benefits of using end-tidal anaesthetic concentrations for titrating anaesthetic depth. While some authors reported that end-tidal isoflurane monitoring does not improve the titration of isoflurane during general anaesthesia [16], other authors reported on a close correlation between the partial pressure of the volatile anaesthetic at the oxygenator exhaust with simultaneously obtained anaesthetic blood partial pressure suggesting that monitoring oxygenator exhaust gas may be used clinically. [17]

In addition, animal responses to noxious stimulation during CPB may be profoundly affected by changes in the plasma concentration, distribution and elimination of administered anaesthetic and analgesic drugs resulting from [15, 18-21]

a) haemodilution and altered plasma protein binding
b) hypotension
c) hypothermia
d) uptake of anaesthetic drugs by the bypass circuit and by the oxygenator
e) frequent use of vasoactive drugs
f) non-pulsatile blood flow during cardiac arrest
g) decreases body uptake of anaesthetic/analgesic drugs with some oxygenators.

During hypothermic CPB the decrease in body temperature will affect the anaesthetic action of volatile agents by increasing the drugs' blood and tissue solubility. [17, 18] In addition, cooling results in MAC reduction of volatile anaesthetics and functional depression of the brain. [22, 23]

Based on these findings, the registration of end-points that are very likely to indicate unconsciousness and thus a lack of conscious perception of pain during surgery would be potentially possible by means of intraoperative monitoring of the cerebrocortical activity, e.g. by recording of the electroencephalogram (EEG). For this purpose, for example, detection of burst suppression (BS) pattern in the analogous EEG or EEG median frequency (MF) below 5 Hz may be used. [12, 24-26]. In addition to MF, other quantitative variables (QEEG) derived from EEG power spectrum analysis such as spectral edge frequency (SEF), distribution of EEG power into different frequency bands (percent of relative delta (□), theta (□), alpha (□), beta (□) power) and power band ratios (□□□□□□□□□□□□□□) may be used to detect increased cerebrocortical activation resulting from noxious stimulation during surgery. [27, 28]The presence of EEG burst suppression pattern during isoflurane anaesthesia in man was reported to indicate an anaesthetic depth which is greater than that necessary to ensure unconsciousness and to prevent recall and awareness. [24] Consequently, the presence of a burst suppression pattern may be used in animals as well to ensure adequate surgical anaesthesia and hence the lack of conscious perception of pain as appearance of BS pattern indicates a diminution of cortical metabolic activity and demand. However, BS pattern may affect the generation of EEG variables such as MF, SEF, etc. and these variables may become invalid.[30] Therefore, future studies are needed in order to determine the value QEEG variables for monitoring adequacy of anaesthetic depth during surgical procedures.

In summary, most clinical signs traditionally used for monitoring depth of general anaesthesia are not sufficient in order to assure lack of conscious perception of pain during specific types of experimental surgeries (e.g. cardiac surgeries, muscle paralysis, long-lasting surgeries). In these cases and based on present knowledge, intraoperative monitoring of the electroencephalogram can provide at least some important information on the likelihood of pain perception which in turn is

very unlikely in the presence of burst suppression pattern.

ANALGESIC REFINEMENT OF PAINFUL EXPERIMENTS IN LABORATORY ANIMALS

Giancarlo Vesce
Department of Clinical Veterinary Sciences University of Napoli "Federico II"
gvesce@unina.it

The use of animal models in biomedical research is a social debate because of their suffering from captivity, manipulations or invasive procedures.
In spite of such concern and of the growing effort to find alternative methods to animal experiments, new techniques and tools have favoured a growing number of in vivo studies.
Small laboratory animals, preferred because of reduced costs, widespread genetic engineering and scaled equipment, favour the design and study of human disease models. To comply with statistical needs, such experiments are frequently run on a large scale, applying estimated anaesthetic protocols to groups of individuals. On the other hand, small species diverge from larger ones and humans for their short life spam and higher metabolic rate, upsetting exact modelling.
Anaesthesia of small laboratory animals is mostly a "one drug" procedure, neglecting the benefits of "balanced anaesthesia". Chemical restraint by hypnotics such as Chloral Hydrate, Tribromoethanol, Alfa-Chloralose and Urethane should not be used for surgical anaesthesia. Depth and duration of anaesthesia must be customized to the specific procedure and tuned to the individual, allowing painless and prompt recovery. Inhalation as well as reversible anaesthetic agents allow for precise recovery timing, avoiding unintentionally prolonged anaesthesia, detrimental for the patient and for the experiment outcome.
Species specific as well as individual analgesic treatment and pain scoring are compulsory to obtain reliable experimental results. Pre-emptive and multimodal analgesia must allow for effective pain prevention and treatment. Skilled sedation, analgesia and anaesthesia are of paramount importance to reduce stress, fear, pain and critical imbalances such as hypothermia, hypoglycaemia, hypoxia and hypercarbia.
Non invasive or mini invasive experimental models should be encouraged, limiting tissue injury. Whenever stressful handling, manipulation, invasive procedures or surgery are anticipated, adequate sedation must be warranted before and after anaesthesia. Under these circumstances the analgesic protocol must be tailored according to the nature, location intensity and duration of painful stimuli.
Quality of pain in experimental models - Due to the enormous amount of diseases and their experimental models it would be out of the reach of this presentation to fit them in specific pain treatment groups. Nevertheless a paradigmatic approach can help grading different experimental painful conditions and their treatment.
Acute pain is more easily anticipated and graded on the basis of the extent of tissue damage, its location and duration of reparative processes. Non invasive procedures such as inflammation, sepsis and shock models impose unbearable suffering seldom treated as such.
Surgery is a fitting example of acute experimental pain. Surgical analgesia must discern damage to soft from hard tissues, somatic from visceral pain, superficial from deep pain, sensitive innervation, movement and weight bearing functions of the injured tissues.
An example is provided by standard invasive cardiovascular research models, such as L.A.D. Coronary Artery ligation or aortic arch stenosis. These procedures are fairly quick, impose limited tissue incision favouring early food intake and behaviour recovery. Nevertheless temporary tracheotomy, intercostals nerves dieresis, severe costal spreading or costotomy and ischemic left ventricle are very painful conditions requiring skilled analgesic treatment rarely adopted in small laboratory animal experiments.
Superficial tissues possess different innervation withholding their lesions from fitting qualitative and quantitative pain grouping. Mechanical, thermal or chemical stimuli trigger such kind of pain

which can be quite severe. Being easily accessible, painful superficial tissues can be promptly treated by topic medication, more direct and effective compared to systemic or regional treatment.
Deep pain must be ranked as somatic or visceral. Somatic, structural, or skeletal pain can originate in muscles, bones, joints and related structures such as fascia, tendons, ligaments and capsules. It can be acute or chronic and can alter animal behaviour when action and position do influence it.
Visceral pain can originate from any of the large body cavities, often bearing an obvious autonomic component. Distension or obstruction of hollow organs and ducts, ischemia, compression, muscular and serosal inflammation give rise to symptoms referred as colic, chest or head aches, which can also be perceived as referred pain.
Neuropathic, neurogenic or central pain is a quality of any kind of pain arising as a consequence of peripheral or central nervous system lesions. It can be very severe and continuous, tends to become chronic and is often characterized by allodynia.
Peripheral neuropathies undergo central events such as wind-up, sensitization and plasticity. Fibromyalgia like muscle pain arising from gamma motoneurons are graded as neuropathic pain.
Central pain has been described in man as a persistent torture featuring dysestesia with spatial summation and hyperpathia with temporal summation.
Experimental models of neuropathic hyperpathia vary from crushing or ligating a peripheral nerve, to lasering the spinal cord of animals after pre-treatment with erythrosin-B. Cancer is an obvious cause of neuropathic pain when nervous structures are affected and in man is known to produce breakthrough cancer pain.
Any kind of pain persisting for a long period of time activates central mechanisms such as wind-up, sensitization and plasticity generating a nociceptive hyperpathia featuring symptoms somewhat similar to neuropathic pain, very difficult to treat. Degenerative or non healing lesions more often of hard tissues are responsible for such kind of pain. Chronic inflammation is a widespread experimental model like primary and metastatic cancer pain, a multifaceted model of human diseases often responsible for chronic pain.
Experimental models of chronic pain impose initial persistent deep acute soreness such as surgical or chemical damage to articular cartilages, producing sudden and sustained inflammation consistent with the degree of the inflicted damage. The assumption that since the animal only shows an initial lameness fading after 2-3 days, conflicts with the histological and clinical evidence of the ongoing chronic disease.
Pain scoring - Analgesia monitoring is compulsory in laboratory animals as well as in any suffering being. Adequate anaesthetic depth must be assessed throughout painful procedures. Recovery must be prompt, gradual and complete, while involuntary excitement must be prevented.
Pain relieving is a multi-step procedure. Effective pain treatment depends on the continuity of the analgesic regimen, as well as on its intensity and on precise, species specific, pharmacokinetic drug scheduling. Pain scoring also necessitates species specific skills; still, a species trained observer has also to face many other behavioural variables such as breed, strain, type of experiment, pain quality and individual response to pain and analgesics.
Pain measurement in non verbal patients it is very subjective and depends on the pain scale used.
Precise pain assessment warrants a proper analgesic regimen. Best results are given by individual patient observation before the experiment and repeated interactive pain scoring throughout the pain treatment period. In any instance, procedures painful to man are equally so in animals.
Choice of the pain scoring scale is critical. No pain scale fulfils all scoring requirements, while some scales can be too complex and time wasting. Ideally more than one scale is needed for a thorough individual pain assessment. Among others, the Dynamic Visual Analogue Scale (DIVAS), the short form Glasgow Composite Pain S., the Melbourne Pain S. and the Colorado S., are most used. As a rule pain scales includes objective parameters such as TPR, weight, food and water consumption and behavioural data, such as activity level, exterior aspect, behavioural traits, vocalizations and when existent, surgical wound or lesions appearence.
“Experiment specific” pain scales allow to focus on the anticipated pain symptoms for an

homogeneous group of individuals saving time and reducing bias.
When allodynia, nociceptive or neuropathic hyperpathia are present or suspected, the mechanical nociceptive threshold can be recorded by Von Frey Filaments applying progressive pressure stimulation from 0,05 g to 300 g.
Pain treatment: Laboratory animals used in medical research must receive skilled analgesic treatment to prevent and cure pain and suffering. The best analgesic approach is set by considering the painful stimuli according to their transduction, transmission, modulation and perception, in order to fulfil the principles of multimodal analgesia combining NSAIDs, local anaesthetics, NMDA and AMPA antagonists, opioids, α-2 agonists and other kind of analgesics.
Elective pain is best prevented at the periphery by local anaesthetics and by the systemic administration of NSAIDs. Central analgesics, NMDA and AMPA antagonists by systemic or Intrathecal route can be combined to easily prevent, block and treat acute pheripheral pain.
The use of local anaesthetics should be encouraged in small laboratory animals, due to their ability to prevent stimuli from reaching central integrating structures, allowing effective analgesia in most painful conditions. If such kind of block is produced at spinal level, sensitive and motor paralysis spreads to dependent regions enhancing and prolonging drug action and promoting a synergistic effect with most central acting drugs. The administration of IV Lidocaine by CRI is an exclusive and very effective exception among all local anaesthetic molecules able to produce central analgesic effect by systemic administration.
Experimental surgery may involve different structures and tissues as in the example on cardiac surgery given above. Such complex pain scenario demands a full set of analgesic measures to prevent and relieve patient suffering: a) pre anaesthetic medication consisting in systemic analgesia by NSAIDs and/or opioids, b) anaesthetic maintenance by potent volatile anaesthetic allowing steady, adequate depth and ease of PPV ventilation, c) local block of intercostals n. or intra-pleural injection of L. A., which can be carried on in the postoperative phase, scheduled according to individual pain score and to agent half-life.
Acute inflammation models such as the Carrageenan, formalin, DSS, endotoxin and other agents or techniques such as colonic infarction models, are a concern, imposing a more cautious strategy to relieve severe acute pain without interfering with the experiment methods and aims.
Minor lesions such as catheterization or invasive instrumentation, skin, eye and mucous membranes incision are promptly reached by local agents providing effective, easy and safe pain prevention and treatment. Severe superficial pain can follow burn lesions, painful scars or skin diseases falling in the nociceptive or neuropathic hyperpathia categories.
Skeletal pain can be quite severe, mainly as a consequence of joints or bone lesions. Weight bearing structures such as hip and legs demand deep planes of anaesthesia and powerful post operative multimodal analgesia.
Visceral pain such as colic, chest or head pain have no chance of peripheral or direct treatment. Such experimental models should either be studied under general anaesthesia, or be prevented and treated by opioids, Ketamine, α-2 agonists or CRI lidocaine. Autonomic signs must be searched for and treated according to their nature to lessen their effects on organs and systems. Craniotomy and intra-cerebral injection or probing must include prevention, monitoring and treatment of increased intracranial pressure.
Neuropathic pain is the worst and most difficult type of pain to treat. Experimental models producing such kind of suffering should be judiciously restricted, warranting ethical authorization upon sound analgesic protocol assurance. Peripheral lesions leading to wind-up, sensitization and plasticity must be prevented by NMDA antagonists. If hyperpathia, allodynia and break trough pain, indicating the existence of neuropathic pain are detected or suspected, must be properly prevented and treated. Opioids, known to be scarcely effective on such kind of pain, are second choice drugs, while Tramadol, some anticonvulsants (gabapentin, pregabalin), tricyclic antidepressants (imipramine) and SSRI (fluoxetine) should rather be dispensed. Intravenous Lidocaine and

localized administration of other local anaesthetic molecules are also known to be effective on neuropathic pain.
Chronic pain models should also be wisely guarded by ethical committees. The acute phase following the initial lesion should be avoided by selecting less cruel and destructive methods such as adjuvant arthritis models. NSAIDs as well as central pain relieving remedies must be adopted to avoid/reduce the symptoms during the acute phase. The chronic pain phase must be treated according to location and quality of pain throughout the experiment on the basis of the harm benefit ratio for animal comfort and experiment methods and aims.
Conclusions - Refinement of anaesthetic and analgesic painful experiments in laboratory animals is a complex task to be accomplished by veterinary anaesthesiologists.
Pre-emptive and multimodal analgesia for a given experiment in a given species be based on stimulus nature and on transduction, transmission, modulation and perception mechanisms. Skilled assessment and treatment of pain must be scheduled on animal metabolic rate and drug half-life.
Individual response to pain and stress must be taken into account in all instances.

“MR ANALYSES OF GLIOSIS AND GLUTAMATE EXCITOTOXICITY IN A MOUSE NEUROPATHIC PAIN MODEL”

Carlo Cavaliere

- Support and Conflicts of Interest: This work was supported by grants from Regione Campania (L.R. N.5 Bando 2003 to M.P.), the Italian Minister of Research and University (PRIN2004 to M.P.), Regione Campania (Prog. Spec art 12 E.F. 2000 to M.P.), and the CNR (Neurobiotecnologie 2003 to M.P.)., and by the Institute of Human Anatomy, Second University of Naples. There are no conflicts of interest.
- Background and Clinical Relevance: Damage to peripheral nerves following either trauma or

disease has several consequences including the development of neuropathic pain. This syndrome, which is persistent and often refractory to conventional analgesic therapy, is characterized by spontaneous burning pain (hyperalgesia) and an exquisite sensitivity to light-touch stimuli, which are perceived as painful (allodynia). Different animal models have been developed: this talk will discuss about astrocytic morpho-functional changes following Chronic Constriction Injury (CCI) of the sciatic nerve.

- Background and Clinical Relevance: In recent years, new technologies have become available for imaging small animals. Noninvasive imaging in small living animal models has gained increasing importance in preclinical research, itself becoming an independent specialty. Recently, we designed a facility for Small Animal Imaging (SAIF), dedicated to research studies on rodents. The SAIF is equipped with several dedicated in vivo small animal imaging instruments like a 7T microMR system (7T Bruker), a microCT scanner (GE eXplore Locus), microPET (Siemens), RX (Multigraph F IMX-84) and microUS (VisualSonics Vevo 770 and now 2100). In this talk, the possibility of in vivo Magnetic Resonance Imaging in a neuropathic pain model will be discuss.
- Background and Clinical Relevance: Gliosis is strongly implicated in the development and maintenance of persistent pain states following chronic constriction injury of the sciatic nerve. Recently, we demonstrate that in the dorsal horn of the spinal cord, gliosis is accompanied by changes in glial amino acid transporters examined by immunoblot, immunohistochemistry and RT-PCR. This talk will be focused on the analysis by imaging techniques of astroglial reaction and of neurotransmitters homeostasis following sciatic nerve injury.
- Results and Interpretation: MR signal intensity in the lumbar spinal cord increases progressively up to the end of the study. This pattern is paralleled by spinal GFAP immunolabeling that increases on pd 7 lasting up to pd 14. Thus in vivo magnetic resonance imaging is able to identify astrocytic reaction following chronic constriction injury of the sciatic nerve.
- Results and Interpretation: Reactive astrocytosis is paralleled by a reduced expression of glial transporters for glycine and glutamate (GlyT1, GLT1) on pd 7 and 14. Consistent with a these phenomena, MR spectrum analysis of lumbar spinal cord showed an increase of Glx peak on pd 7 and 14. At the same time points, HPLC analysis revealed a net increase in glutamate and glycine concentration in lumbar spinal cord tissue from neuropathic mice. In vivo magnetic resonance imaging is able to quantify neurotransmitters level alterations and so functional consequences of reactive astrocytosis.
- Results and Interpretation: This presentation will report new data showing that following chronic constriction injury gliosis, and the concurrent glial cytoskeletal rearrangement, correlates with a marked decrease in glial aminoacid transporters, and determines a net increase of neurotransmitters at spinal cord level, as revealed by MRS and HPLC analyses. We

speculate that these phenomena could contribute, via NMDA receptor overstimulation, to generate changes in synaptic functioning responsible for persistent pain maintenance.

- Future Directions: Understanding the cellular and molecular substrates that maintain neuropathic pain will provide opportunities to develop targeted drugs and so more effective therapies to improve neuropathic pain management.

ANALGESIC STRATEGIES IN EXPERIMENTAL SWINE SURGERY MODELS

S.Castaldo DVM and C.Attanasio DVM, PhD

Ospedale Cardarelli Center of Biotechnologies, 9 Via Cardarelli, 80131, Naples, Italy.
castaldo@cb.ospedalecardarelli.it

The Center of Biotechnologies (CB) of Ospedale "A. Cardarelli" in Naples is equipped with an "animal lab", authorized by the Italian Ministry of Health, for training in surgery and microsurgery as well as research activities. In this context animal models for biomedical and pre-clinical studies are developed and tested [1]. The analgesic strategy underlying our approach to invasive and painful procedures has been developed with special reference to suffering prevention and experiment refinement, reported by Russel and Burch through the 3 R (replacement, reduction, refinement) concept on animal welfare. Over the course of 2009, greater then 200 pigs were anesthetized for experimental studies at the CB. Among this group we elected to use different analgesic strategies in diverse protocols depending on whether the experiments was designed for research or training purposes [2]. After arrival at the CB, animals are allowed to acclimate for 1-2 days and provided with health monitoring, food and water ad libitum. Pigs were fasted for 8-12 hours before surgery. On the scheduled day of surgery each pig was premedicated, based on weight, with a combination of tiletamine and zolazepam administered via an intramuscular injection. This mode of delivery results in a faster induction and uses a lower injection volume compared to azaperon and ketamine when used for the same purpose. Anaesthetic induction is then performed using propofol and ketamine administered intravenously and followed by endotracheal intubation for inhaled isoflurane administration as needed. Throughout the experiment hemodynamic and biochemical parameters are continuously monitored. Maintenance anaesthesia is provided using propofol or isoflurane depending on the experimental setting. Analgesia management is specifically designed and optimized for each procedure. Ketamine is extensively associated to analgesic drugs in order to better control adverse effects [3]. Transdermal patch for analgesic delivery has been abandoned because of the wide range of unexpected individual responses with a high risk of overdose. During videolaparoscopic procedures we suggest an intravenous bolus of butorphanol for its fast action and simple management, moreover its effective volume may be decreased by using xylazine which can reduce the economic burden. Our experience has led us to recommend carprofen for biomaterials related research due to its long-lasting analgesic effect; 24 hours, versus 6 hrs with butorphanol, as well as the added benefit of being able to administer with food, thus avoiding stressful manipulations. Throughout invasive procedures such as osteosynthetic implants a single bolus of butorphanol administered intravenously enhances carprofen effectiveness. In the specific case of training in surgery, just after the anaesthesia induction, ketorolac via intramuscular injection enables to induce a "delayed", long-lasting analgesia which is perfected by butorphanol administration as needed [4].
Taken together, our findings provide the community with important information related to appropriate and effective anaesthetic and analgesic for use in large animal models.

Nel nostro Paese la protezione degli animali allevati o custoditi per la produzione di derrate alimentari, lana, pelli, pellicce o per altri scopi agricoli, inclusi pesci, rettili e anfibi, è regolamentata dal decreto legislativo n. 146/2001, attuazione della direttiva 98/58/CE e da norme specifiche relative all'allevamento dei vitelli, dei suini, delle galline ovaiole.
La decisione n. 778/2006, entrata in applicazione dal 1° gennaio 2008, stabilisce che le ispezioni per il benessere animale debbano riguardare tutte le specie d'allevamento che rientrano nel campo di applicazione della direttiva 98/58/CE e non solo vitelli, suini e galline ovaiole, inoltre detta regole per armonizzare la raccolta delle informazioni nel corso delle ispezioni e le modalità di comunicazione delle informazioni stesse alla Commissione europea.
Il presupposto fondamentale su cui si basa detta decisione è che le difformità applicative delle norme in materia di benessere animale potrebbero da una parte compromettere il benessere degli animali allevati e dall'altra provocare una distorsione nella leale concorrenza di mercato.
Per quanto concerne la protezione degli animali durante il trasporto il Regolamento (CE) n. 1/2005 ha determinato notevoli cambiamenti particolarmente evidenti in realtà come quella nazionale caratterizzata dalla notevole movimentazione di animali vivi da altri Paesi comunitari.
Relativamente alla protezione degli animali durante la macellazione è stato recentemente approvato il regolamento sulla protezione degli animali durante l'abbattimento che abrogherà la direttiva 93/119/CE.
Il Ministero della salute, in applicazione della legislazione UE nonché in coerenza con il Piano d'azione comunitario per il benessere animale 2006 – 2010 e nel rispetto dei principi enunciati dal trattato di Lisbona, che riconosce agli animali la qualità di esseri senzienti, ha messo in atto numerose iniziative che vanno dall'implementazione e programmazione dei controlli alla formazione di tutti gli operatori del settore.
In particolare è stato emanato il Piano nazionale per il benessere degli animali in allevamento avviato con una fase sperimentale nell'agosto 2008. Il PNBA, periodicamente aggiornato, è stato elaborato da un gruppo di lavoro istituito presso la Direzione Generale della sanità animale e del farmaco veterinario di cui fanno parte rappresentanti dei Servizi Veterinari delle Regioni e Province autonome nonché del Centro di Referenza nazionale per il benessere animale.
Il "piano nazionale per il benessere animale (PNBA)" nasce non solo dall'esigenza di ottemperare alle disposizioni nazionali e comunitarie ma anche dalla necessità di rendere uniformi le modalità di esecuzione e la programmazione dei controlli. Partendo dal presupposto di base secondo il quale è necessario migliorare la formazione dei medici veterinari e degli allevatori relativamente alle tematiche di benessere animale, si è ritenuto indispensabile individuare la formazione stessa come obiettivo prioritario del PNBA, in quanto solo attraverso il miglioramento della conoscenza è possibile garantire il rispetto delle norme vigenti e l'applicazione di tecniche di allevamento più rispettose delle esigenze etologiche delle specie allevate.
Le iniziative di formazione finanziate e coordinate dal Ministero si prefiggono, pertanto, l'obiettivo di creare un sistema nazionale che garantisca la conoscenza ed il rispetto delle norme di benessere animale da parte di tutti gli attori della filiera.
Dal 2010 il PNBA prevede anche una programmazione minima dei controlli per la verifica delle disposizioni concernenti il benessere degli animali durante il trasporto e nella macellazione.
Nel prossimo futuro il benessere animale, già oggi ricompresso tra gli obiettivi principali della politica europea, troverà sempre maggiore spazio anche in considerazione dell'aumento della sensibilità dei cittadini europei su tali tematiche e del riconoscimento dell'esistenza di uno stretto legame tra benessere, sanità animale e sicurezza alimentare. In ambito UE entro il 30 giugno 2010 in tutti i Paesi membri dovrà essere data attuazione alla direttiva concernente il benessere dei polli da carne, mentre numerose altre iniziative sono in itinere in Europa, non solo all'interno della

Comunità ma anche nel contesto del Consiglio d'Europa e dell'OIE.

I medici veterinari, sia pubblici che privati, e tutti gli attori della filiera devono essere pronti a questa profonda evoluzione che comporta sicuramente un cambiamento culturale e un notevole impegno, anche sul piano economico, ma che a lungo termine condurrà al miglioramento in termini di qualità delle nostre produzioni zootecniche.

L' APPROCCIO IMMUNOLOGICO ALLA VALUTAZIONE DEL BENESSERE ANIMALE

Massimo Amadori

Laboratorio di Immunologia Cellulare,
IZSLER, Brescia

Le risposte infiammatoria, immunitaria e da stress costituiscono un unico complesso ancestrale di risposte biologiche sovrapposte, finalizzate alla neutralizzazione di *noxae* che turbino l'equilibrio omeostatico dell'organismo animale. Tali risposte si sono via via differenziate nel corso dell'evoluzione filogenetica sino all'assetto attuale nei vertebrati superiori. Al di là di tale aspetto, la conseguenza più importante che deriva da tale concetto è che sussiste una notevole sovrapposizione tra meccanismi di risposta a "stressor" infettivi di natura microbica e meccanismi implicati nella risposta a "stressor" di natura non infettiva, associati al processo di adattamento ambientale. Si può così comprendere pertanto come una citochina del sistema immunitario, l'interferone alfa, non sia solo implicato nella risposta ad agenti virali, ma anche agli stress da trasporto e da svezzamento precoce nei suini; l'importanza di tale citochina per l'omeostasi metabolica dell'ospite è inoltre provata dalla sua presenza costitutiva, non indotta, in organi e tessuti, evidenziata anche nella specie suina. Il sistema immunitario partecipa pertanto con il sistema neuro-endocrino ai processi di regolazione omeostatica dell'organismo animale. Aspetti importanti della scienza immunologica rientrano così a pieno titolo nella disciplina denominata "fisiologia dell'adattamento". A seguito ad esempio di uno stress da trasporto e da formazione dei nuovi gruppi in allevamento, l'adattamento si accompagna ad un progressivo ripristino di fondamentali condizioni di normalità dell'etogramma e della regolazione metabolica, anche a livello dei parametri correlati alla competenza immunitaria nei confronti dei patogeni ambientali. Tale competenza è pertanto un indice preciso del livello di benessere animale, inteso per l'appunto (secondo la corrente di pensiero funzionalistica) come la condizione di un individuo per quanto concerne i suoi tentativi di adeguarsi all'ambiente. E' evidente infine la correlazione tra competenza immunitaria nei confronti dei patogeni ambientali e problematiche di sanità animale. Sulla base di tali presupposti, l'immunologia veterinaria è in grado di fornire contributi decisivi nei settori del benessere e della sanità animale, in ambiti che vanno dai meccanismi di risposta immunitaria a infezioni naturali e vaccinazioni, sino ai fini meccanismi di immunosoppressione e di alterata omeostasi della risposta infiammatoria, che preludono all'insorgenza di diverse patologie condizionate di natura infettiva o dismetabolica. E' questo il caso di molti problemi sanitari della bovina da latte nel periodo di transizione (3 settimane prima e dopo il parto), alla base dei quali si osserva una grave disregolazione del processo flogistico innescato da citochine pro-infiammatorie del sistema immunitario. Sulla base di queste analisi, il veterinario deve saper proporre idonei interventi di igiene zootecnica atti a favorire l'adattamento ambientale degli animali; tali interventi sono finalizzati in primo luogo alla prevenzione di risposte da stress cronico che possono a loro volta sfociare in patologie condizionate. In tale contesto, anche gli interventi di immunomodulazione mirata possono giocare un ruolo sicuramente importante, visto che la selezione genetica per elevate produzioni ha in genere determinato l'emergere di fenotipi animali meno in grado di adattarsi a condizioni ambientali non ottimali.

PROBLEMI PRATICI DI ADATTAMENTO ALL'AMBIENTE DELLE BOVINE DA LATTE CON PARTICOLARE RIFERIMENTO ALLO STRESS DA CALDO

L'adattamento della bovina da latte all'ambiente di allevamento comporta l'attivazione di una serie complessa di processi di natura comportamentale, neuroendocrina, metabolica ed immunologica che può compromettere in maniera significativa il mantenimento di una condizione ottimale di benessere e di salute.
Numerose esperienze di carattere sperimentale hanno evidenziato come le condizioni di caldo ambientale tipiche della stagione estiva costringano la bovina a mettere in atto processi che hanno come obiettivo fondamentale quello di evitare l'innalzamento della temperatura corporea (ipertermia) e che l'attivazione di tali processi può avere delle ripercussioni negative sullo stato di benessere e di salute, sulle performance riproduttive e produttive e sulle aspettative di vita (1).
L'alterazione dello stato metabolico e della funzionalità del sistema immunitario possono essere causa rispettivamente di aumento dell'incidenza di dismetabolie (alterazioni dell'equilibrio acido-basico, chetosi, *fatty liver*), di alterazioni dello stato ossidativo e di patologie di natura infettiva (2, 3, 4); l'alterazione delle performance riproduttive si sostanzia in una maggiore incidenza di calori silenti, di ritorni in calore e in un conseguente allungamento degli intervalli interparto (5, 6); il deficit produttivo può tradursi in riduzione sia della quantità sia della qualità del latte prodotto (7).
Le ipotesi avanzate per giustificare la maggiore incidenza di alcune infezioni durante il periodo caldo estivo sono relative alla possibilità che le condizioni di clima caldo possano facilitare la sopravvivenza e la moltiplicazione di microrganismi patogeni nell'ambiente di allevamento e/o essere causa di una minore efficienza dei meccanismi difensivi che l'animale attiva nei confronti delle aggressioni da parte di agenti infettanti. A tale ultimo riguardo, in uno studio condotto nel corso dell'estate 2003 (8), noi stessi abbiamo evidenziato una profonda alterazione dei meccanismi difensivi in bovine peripartorienti che ha riguardato la risposta immunitaria di tipo cellulo-mediata. Oltre a determinare una maggiore vulnerabilità degli animali nei confronti di alcuni agenti patogeni viventi l'immunodepressione riconducibile a situazioni di stress caldo intenso, come quello che ha caratterizzato il periodo estivo dell'anno 2003, potrebbe pure associarsi ad una ridotta efficacia degli interventi vaccinali nonché a diminuzione dell'attendibilità di test diagnostici basati sulla valutazione della reattività del sistema immunitario (intradermotubercolinizzazione).
Infine, in uno studio di campo recente eseguito in Pianura Padana sono stati individuati valori soglia di una variabile che consente di valutare congiuntamente i valori della temperatura e dell'umidità relativa (Temeperature Humidity Index, THI) al di sopra dei quali il rischio di morte per la bovina da latte aumenta in maniera significativa (9).
Le strategie attuabili per facilitare l'adattamento delle bovine da latte alle condizioni di caldo ambientale sono riconducibili sostanzialmente all'effettuazione di interventi di natura ambientale (raffrescamento) o alimentare (formulazione di razioni *ad hoc* per il periodo estivo) (10, 11).
La realizzazione di modifiche delle strutture e del management di allevamento e la messa a punto di sistemi di allerta meteo potranno consentire agli allevatori di predisporre per tempo gli interventi necessari per mitigare gli effetti di eventi climatici estremi che con frequenza sempre maggiore tenderanno a verificarsi nel corso dei prossimi decenni.

VALUTAZIONE DEL BENESSERE ANIMALE IN ALLEVAMENTO CON IL METODO WELFARE QUALITY®

G. De Rosa

Dipartimento di Scienze del Suolo, della Pianta, dell'Ambiente e delle Produzioni animali, Università degli Studi di Napoli "Federico II", Via Università 133, 80055 Portici (NA) - Italy.

Corresponding author: Giuseppe De Rosa – Email: giderosa@unina.it

Negli ultimi anni, in Europa sono stati messi a punto diversi schemi di valutazione del benessere animale al fine di consentire al consumatore di acquistare prodotti ottenuti da soggetti che abbiano avuto la possibilità di godere di un "elevato grado di benessere". In tali schemi, proposti da diversi gruppi di interesse (produttori, grande distribuzione, catene di ristorazione, organizzazioni non governative, ecc.), viene preso in considerazione un certo numero di parametri che varia da uno schema ad un altro, mettendo in evidenza la mancanza di standard europei, sia per la valutazione del benessere, sia per l'acquisizione di informazioni oggettivamente trasferibili e facilmente comprensibili dai consumatori (certificazione dei prodotti). Pertanto, a livello europeo è stata avvertita l'esigenza di uniformare le varie procedure. In questo contesto, il progetto Welfare Quality®, la cui denominazione ufficiale è "*Integration of animal welfare in the food quality chain: from public concern to improved welfare and trasparent quality*", della durata di 5 anni (2004-2009), ha perseguito l'obiettivo di mettere a punto un sistema di valutazione del benessere a livello aziendale e di individuare specifiche strategie per migliorare le condizioni di allevamento di bovini (vacche da latte, manze, vitelli a carne bianca e vitelloni), suini (scrofe, suinetti, suini da ingrasso) e avicoli (galline ovaiole e broilers). Sistema di valutazione che potrà essere utilizzato anche come strumento consultivo dagli allevatori per identificare, prevenire o risolvere problemi tecnico-gestionali influenzanti il livello di benessere degli animali allevati. Nel 2007 sono rientrate nel progetto anche le bufale da latte. Gli istituti di ricerca europei coinvolti sono stati 50.

Del benessere esistono numerose definizioni, ma, in termini generali, un elevato livello di benessere presuppone buone condizioni fisiche e mentali dell'animale. Molti sono concordi nel ritenere che il benessere sia multidimensionale, dipendente da molti aspetti della vita, compresi gli eventi e gli stati affettivi positivi e negativi vissuti da un individuo e, in particolare: emozioni negative come la fame, la sete, il dolore, la paura, traumi e malattie, ecc. ed esperienze positive come quelle prodotte dall'espressione di comportamenti naturali (riproduttivo, sociale, materno, ecc.). Una valutazione generale del benessere, pertanto, deve tenere conto di tutti questi aspetti, basandosi sulle conoscenze scientifiche relative a questa problematica.

Nel progetto Welfare Quality® sono stati individuati 12 criteri da prendere in esame in un qualsiasi sistema di monitoraggio del benessere (Tabella 1). Al fine di ridurre il loro numero e facilitarne la comprensione, tali criteri di benessere sono stati riuniti in 4 principi in funzione dei seguenti aspetti:

1. gli animali sono alimentati e abbeverati adeguatamente?
2. gli animali sono stabulati in modo razionale?
3. gli animali presentano un buono stato di salute?
4. il comportamento degli animali riflette stati emozionali positivi?

Tabella 1 - Schema per la valutazione del benessere a livello aziendale.

Principio	Criterio	Esempi di indicatori
Alimentazione	**1.** soddisfacimento delle esigenze nutrizionali	*Body Condition Score*
	2. soddisfacimento delle esigenze idriche	numero e pulizia degli abbeveratoi
Stabulazione	**3.** comfort durante il riposo	frequenza delle differenti posture
	4. comfort termico	polipnea, brividi e orripilazione
	5. facilità di movimento	tipologia di stabulazione
Salute	**6.** assenza di lesioni	valutazione dei danni a carico del tegumento presenza di zoppia
	7. assenza di malattie	diarrea, parassiti esterni, mortalità
	8.assenza di dolore indotto dalle pratiche manageriali	Mutilazioni routinarie (recisione della coda, decornazione, ecc.)
Comportamento	**9.** espressione del comportamento sociale	*allogrooming* , comportamento agonistico
	10. espressione di altri comportamenti	accesso al pascolo, comportamenti anomali
	11. rapporto uomo-animale	distanza di fuga, test di avvicinamento
	12. assenza di paura	valutazione qualitativa del comportamento

L'impostazione del metodo è stata sottoposta all'esame di un gruppo di consumatori che ha manifestato piena approvazione. Il passo successivo è stato quello di definire in che modo debbano essere valutati i singoli elementi del benessere animale: gli animali differiscono in relazione al patrimonio genetico, alle esperienze acquisite, al temperamento e ad altri fattori, per cui possono percepire lo stesso ambiente in modo diverso. Così, la rispondenza a determinati requisiti riguardanti la tipologia di stabulazione, la disponibilità di spazio, il tipo di pavimentazione, la facilità di assunzione dell'alimento e dell'acqua, ecc. o quelli relativi al management (strategie riproduttive, piani sanitari, routine di mungitura, ecc.) non sempre costituisce garanzia di un buon benessere in una particolare situazione. Pertanto, è stato convenuto di effettuare la valutazione del benessere fondamentalmente sulla base di misure rilevate direttamente sugli animali (stato di salute, comportamento, ecc.). Sono stati pertanto identificati, per ciascuna specie animale, i potenziali indicatori da utilizzare, programmando nel contempo le ricerche da condurre per aumentarne l'affidabilità. Nel sistema di monitoraggio è stato previsto anche l'esame di elementi tecnici e strutturali (tipo di ricovero, densità di allevamento, ecc.) e del management (strategie riproduttive, piani sanitari, ecc.), che può contribuire alla individuazione delle cause quando l'osservazione degli animali evidenzia che il livello di benessere in una determinata azienda è scarso o perché può risultare utile per l'identificazione dei fattori di rischio per problemi di benessere futuri. Tutti gli indicatori inseriti nello schema di monitoraggio Welfare Quality® sono stati sottoposti a verifica per quanto riguarda la validità (relazione esistente tra la variabile misurata e ciò che essa dovrebbe valutare in termini di benessere), la ripetibilità (grado di concordanza dei risultati ottenuti in differenti misurazioni) e l'applicabilità (facilità di rilievo). Gli indicatori basati sull'osservazione diretta degli animali maggiormente rispondenti ai suddetti requisiti sono stati rigorosamente valutati

sotto l'aspetto scientifico per verificare se il sistema di monitoraggio soddisfacesse le aspettative dei consumatori e dei produttori. Il sistema di monitoraggio è stato poi testato in allevamenti e impianti di macellazione di diversi paesi dell'UE (Italia, Spagna, Francia, ecc.).
Per poter fornire informazioni ai consumatori sullo stato di benessere degli animali, i risultati sono stati integrati in una valutazione complessiva secondo i metodi messi a punto nella teoria multidecisionale. Gli indicatori inclusi nello stesso criterio sono stati combinati affinché possa ottenersi un unico valore compreso tra 0 e 100. I punteggi bassi corrispondono a livelli di benessere inadeguati, al contrario di quelli più alti. Successivamente, i criteri di ciascun principio sono stati aggregati utilizzando metodi che limitino la compensazione. Infine, si otterrà un giudizio globale che potrà rientrare in quattro diverse categorie di benessere. I diversi passaggi (dagli indicatori al giudizio globale) sono stati discussi e definiti con il contributo di tutti i rappresentanti della filiera produttiva (allevatori, consumatori, ricercatori, politici, ecc.).

ADATTAMENTO ALL'AMBIENTE DI ALLEVAMENTO DELLA SPECIE BUFALINA

E. De Carlo

Istituto Zooprofilattico del Mezzogiorno- Centro di Referenza Nazionale sull'igiene e le tecnologie dell'allevamento e delle produzioni bufaline- Sezione di Salerno
esterina.decarlo@cert.izsmportici.it

Caratteristiche generali della specie

In Italia l'allevamento della bufala è presente ormai in tutte le regioni, con valori che oscillano dal 73,3% del patrimonio nazionale per la Campania, al 18,2% per il Lazio e di poco al disopra del 2% per la Lombardia e la Puglia, mentre la restante percentuale è distribuita su tutto il territorio nazionale. L'allevamento di questa specie è finalizzato soprattutto alla produzione di un particolare formaggio fresco a pasta filata, denominato mozzarella di bufala, a cui è riconosciuta la Denominazione di Origine Protetta se prodotta nelle aree geografiche incluse nel Disciplinare di produzione.

Per loro natura, i bufali sono animali sociali che vivono in allevamenti di varie dimensioni nel rispetto di una rigida gerarchia di dominanza. Nel corso dell'evoluzione, i bufali hanno acquisito alcune caratteristiche morfologiche che consentono loro di vivere in zone calde e umide. Dopo una gestazione di circa 310 giorni, si ha la nascita di un solo vitello o, più raramente, di due gemelli (0.6%), dal peso variabile tra i 35 e i 39 kg, anche se negli ultimi anni il peso alla nascita è aumentato.

Principali fattori che influenzano il benessere della bufala

L'allevamento delle bufale da latte costituisce una tradizionale attività svolta per secoli secondo sistemi estensivi in zone paludose e marginali dell'Italia centro-meridionale. L' introduzione di tecniche di allevamento più avanzate (mungitura meccanica, allattamento artificiale dei vitelli, stabulazione libera con cuccette, nuovi criteri di razionamento, ecc.), anche se messe a punto per i bovini da latte e perciò non sempre adeguate alle esigenze della bufala, ha indotto un notevole incremento del livello produttivo, suscitando un notevole interesse per questa specie. Ma la rapida intensivizzazione delle tecniche di allevamento ha esposto questi animali a repentini cambiamenti e a vari stressori di natura fisica e psicologica che prima non interessavano questa specie.

Trattandosi di una specie evolutasi in zone calde e umide, si è reso necessario per la bufala acquisire alcune caratteristiche morfologiche e funzionali che le consentissero di vivere bene e produrre in zone con una temperatura tra 15° e 30°C. Il processo evolutivo ha reso pertanto questa specie più attiva e più produttiva proprio nei mesi più caldi.

La fertilità della bufala infatti migliora al diminuire delle ore di luce, indipendentemente dalla temperatura, ovvero è una specie a fotoperiodo negativo, con il picco di fertilità, nelle mandrie destagionalizzate, tra luglio e agosto, contrariamente alla bovina che ha una fertilità a fotoperiodo positivo (la bovina tra luglio ed agosto fa registrare i più bassi tassi di concepimento) e con picco settembre-gennaio nelle mandrie non destagionalizzate (1). In condizioni di monta naturale, ovvero senza adottare accorgimenti che mirano a modificare la stagionalità, come la tecnica di destagionalizzazione dei parti, a Nord dell'equatore, sia nelle aree temperate sia nelle aree tropicali, la stagione dei parti è compresa tra luglio e dicembre-gennaio, periodo in cui si registra circa il 70% dei parti. Il restante 30% si distribuisce tra febbraio e giugno. In definitiva, proprio quando la fertilità della bovina da latte è migliore (gennaio - giugno) quella della bufala è peggiore. Quando si adotta la tecnica di destagionalizzazione dei parti, la maggior parte dei concepimenti nella bufala si registra tra luglio e settembre, periodo dell'anno in cui la fertilità della bovina fa registrare i valori più bassi. Ne deriva pertanto che la fertilità va valutata in funzione della stagionalità della mandria e/o dell'adozione o meno della destagionalizzazione dei parti. E' ovvio che risultano più fertili le mandrie in cui non viene modificata la stagionalità rispetto a quelle in cui il calendario dei parti viene modificato in funzione della richiesta di mercato (2). Pertanto, la fertilità va valutata in una

mandria a parità di tecnica adottata. La tecnica di destagionalizzazione comunque non influisce negativamente sullo stato di benessere dell'animale, ma la nascita di vitelli nei mesi più freddi dell'anno è da tenere in conto quando si progetta la stalla, poiché bisogna preventivare la costruzione di vitellaie particolarmente idonee a ricoverare i nuovi nati per proteggerli dal clima rigido.Anche il picco produttivo si colloca nel periodo estivo, ovvero tra giugno e agosto, contrariamente a quanto accade nel bovino, proprio quando T° e THI sono simili a quelli dei paesi tropicali, e anche l'assunzione di sostanza secca non viene penalizzata dalle alte temperature ambientali, sempre che, come già detto, vengano forniti adeguati mezzi di protezione.
Nella specie bufalina è stato osservato che a parità di spazio (m^2/capo), di ordine di parto (calving parity) e di razionamento, la produzione lattea a 135 giorni dal parto, che corrisponde a metà lattazione, non viene influenzata negativamente dalle temperature estive bensì da quelle invernali (3). Durante il periodo invernale, a una minore produzione di latte corrisponde una maggiore assunzione di sostanza secca cui consegue però una peggiore conversione di sostanza secca in latte. E' verosimile che parte della sostanza secca, e quindi l'energia in essa contenuta, venga utilizzata per far fronte agli accresciuti fabbisogni derivanti dalle basse temperature ambientali, proprio perchè il bufalo è una specie che predilige il caldo. E' stata osservata una bassa assunzione di sostanza secca nel periodo marzo – maggio, ascrivibile alla bassa produzione di latte, quindi l'incremento delle ore di luce giornaliera probabilmente penalizza non solo l'attività riproduttiva ma anche quella produttiva. Inoltre, contrariamente a ciò che avviene nella vacca da latte, la bufala non modifica in senso negativo la qualità del latte estivo al punto che la mozzarella prodotta d'estate è addirittura più sapida e gradita al consumatore.
La maggiore assunzione di sostanza secca durante l'estate potrebbe dipendere anche dal fatto che il numero di passi giornalieri (registrati con il podometro) aumenta all'aumentare delle ore di luce (aprile – luglio) sia nelle primipare sia nelle pluripare, comportando un maggior dispendio energetico. Tale comportamento potrebbe essere determinato anche da una maggiore attività sessuale nel periodo estivo e a una maggiore percentuale di concepimento.
Se ne deduce che le basse temperature influiscono negativamente su produzione e riproduzione del bufalo. Il freddo infatti incrementa la perdita di calore corporeo e la mortalità neonatale ed influisce sulla funzionalità tiroidea. Elevati livelli di T4 influenzano negativamente estrogeni e progesterone nel liquido follicolare, riducendo la fertilità (4).
Ma oltre al freddo, anche l'alta temperatura ambientale, in associazione con un elevato THI (temperature humidity index) e in assenza di adeguate strutture, può costituire un fattore stressogeno. Infatti, la cute pigmentata protegge i bufali dall'azione dannosa dei raggi gi ultravioletti, ma la densità dei peli negli adulti è pari all'incirca a 1/8 di quella dei bovini, 394 follicoli/cm2 vs 2893 del bovino, e anche il numero delle ghiandole sudoripare e sebacee è notevolmente inferiore rispetto al bovino. Tuttavia, la secrezione di sebo nei bufali è più elevata e svolge una funzione protettiva sulla pelle quando gli animali s'immergono nel fango. D'altro canto, la pelle dei bufali presenta uno spessore maggiore di quella del bovino; infatti, lo strato corneo misura circa 11µm vs 5µm nel bovino e svolge essa stessa una funzione di protezione della superficie corporea, quasi completamente sprovvista di peli, contro agenti meccanici e chimici, soprattutto quando gli animali sono immersi nel fango. Da quanto detto si evince che la possibilità di immergersi in acqua o fango e l'ombreggiamento costituiscono delle condizioni fondamentali per la termoregolazione del bufalo durante la stagione estiva (5). È pertanto indispensabile la presenza negli allevamenti di pozze, vasche, doccette e tettoie.
La bufala, se fornita di acqua in cui immergersi, migliora la produzione lattea ed incrementa la sua attività riproduttiva, come è attestato da numerosi studi che dimostrano anche come, nei gruppi provvisti di pozze, sia significativamente più elevata la produzione lattea media individuale senza differenze qualitative del latte prodotto, e sia minore la percentuale di bufale non gravide con un intervallo parto-concepimento più breve (6,7,8). In bufale allevate senza vasca si è inoltre dimostrato un più alto tasso di mortalità embrionale e/o cicli anomali, senza contare che la presenza d'acqua induce le bufale ad interagire di più con i consimili, favorendo più movimento, più

esplorazione e più interazioni sociali, che sono attività indicatrici di un buon livello di benessere.
Un altro elemento importante per il benessere di questa specie, che non ha subito la stessa pressione di selezione della bovina da latte, è la disponibilità di spazio.
Tutti gli studi condotti sul bufalo hanno dimostrato che la maggiore disponibilità di spazio, che a nostro parere in un allevamento intensivo deve comunque essere il più vicino possibile ai 20 m^2/capo, corrisponde sempre a una produzione di latte maggiore e a una maggiore assunzione di sostanza secca, a un aumento della fertilità della mandria e a una diminuzione del periodo di interparto, sempre in maniera proporzionale allo spazio disponibile (3).
L'aumento produttivo registrato negli studi effettuati è probabilmente da attribuire a una migliore condizione di benessere di tutti i soggetti allevati.
Una maggiore disponibilità di spazio potrebbe agire in diversi modi e, principalmente, riducendo la pressione gerarchica, che spesso si manifesta nella specie bufalina con fenomeni di aggressività nei confronti dei soggetti più deboli, aumentando la possibilità della ginnastica funzionale e migliorando le condizioni ambientali in termini di riduzione dei gas derivati dalle fermentazioni delle deiezioni prodotte.
La riduzione dello spazio determina anche nei vitelli alterazioni della risposta comportamentale e fisiologica (9).
Da quanto detto si evince che la produttività della bufala e la sua resa economica sono influenzate dalla possibilità di riprodurre in allevamento una situazione naturale. Pertanto, nella progettazione dell'ambiente d'allevamento del bufalo è importante garantire una stabulazione in grado di offrire confort e movimento commisurati alle esigenze dell'animale.

Dati di laboratorio

L'incremento delle performance produttive comporta per i bufali, come avviene per le altre specie sottoposte ad allevamento intensivo, un obiettivo aumento del rischio di patologie conclamate o di gravi disfunzioni metaboliche. Infatti, la sovrastimolazione dei meccanismi fisiologici di omeostasi favorisce l'insorgenza d'immunosoppressione, che predispone alle malattie. Ogni tentativo di sovraccaricare le prestazioni fisiologiche dell'animale costituisce un elemento di stress, unitamente ad ogni tipo di sollecitazione ambientale che coinvolga i sistemi di controllo e di regolazione.
La valutazione del management aziendale, del tasso di rimonta e delle produzioni, associata all'osservazione comportamentale degli individui, non costituisce da sola un sistema obiettivo di valutazione del benessere, poiché è necessario mettere a punto dei sistemi in grado di fornire un accertamento puntuale e tempestivo del livello di benessere. In tal senso sarebbe necessario un approccio combinato multidisciplinare, basato su competenze di clinica, zootecnia, etologia e immuno-biochimica, al fine non più di verificare e controllare lo stato di benessere, bensì di prevenire lo stato di stress e mantenere in piena efficienza le competenze immunitarie dei soggetti.
In tal senso rivestono un ruolo di fondamentale importanza le indagini di laboratorio atte a rivelare lo stato immunitario dei soggetti. Lo studio dei parametri d'immunità innata, non adattiva, che condiziona l'interazione con i più comuni patogeni ambientali, può soddisfare la necessità di conoscere la predisposizione dei soggetti a sviluppare malattie condizionate da eventi stressanti di qualsivoglia natura (10). Quindi, sarebbe bene corredare le valutazioni di tipo etologico e zootecnico con valutazioni di laboratorio a carattere immunologico, ematologico e chimico-clinico, atte a rilevare l'entità dello sforzo di adattamento ambientale da parte degli animali e le alterazioni correlate a tale sforzo.
Nella specie bufalina, oltre alle indagini ematologiche e chimico-cliniche, effettuate di routine dai clinici più attenti, risultano applicabili anche alcuni dei parametri immunitari già da tempo disponibili per le specie di maggiore interesse zootecnico.
Grazie al lavoro di collaborazione iniziato nel 2007 con il Centro di Referenza Nazionale Benessere Animale, nei laboratori del Centro di Referenza Nazionale sull'igiene e le tecnologie dell'allevamento e delle produzioni bufaline, sono stati applicati sui sieri bufalini i metodi di prova per la titolazione del lisozima, la titolazione semiquantitativa del complemento emolitico, la

determinazione della battericidia sierica in micrometodo e il dosaggio dell'aptoglobina. Tutti i parametri indagati sembrano poter essere applicati con successo alla specie bufalina, anche se la determinazione degli standard di riferimento specifici per la specie è ancora oggetto di studio; infatti, sarebbe un grave errore assimilare il bufalo al bovino anche riguardo ai parametri di laboratorio. Infatti, dagli studi effettuati in diverse tipologie di allevamento, di categorie di età e di produttività, risulta che i livelli di aptoglobina sono in media molto più elevati dei valori riportati in letteratura per i bovini, e quelli del lisozima sono più vicini ai valori dei bovini da carne che a quelli delle vacche da latte. Considerazioni simili sulla difformità dei valori possono essere fatte per la battericidia sierica che nel bufalo presenta valori inferiori a quelli dei bovini.
Secondo degli studi effettuati, in tutte le categorie di età allevate in maniera estensiva si è rilevata una più alta concentrazione di complemento emolitico rispetto a quelle tenute in allevamento intensivo. Questi dati indicano che gli animali che hanno una maggiore disponibilità di spazio hanno anche una migliore capacità di affrontare la comparsa e la severità di eventuali infezioni. Alla stessa maniera, i livelli di aptoglobina sono risultati più elevati in un allevamento intensivo che, per motivi di gestione, veniva sottoposto a numerose manipolazioni da parte degli operatori sanitari, eventi di certo stressogeni. Inoltre, i livelli di aptoglobina sono risultati più alti in inverno in tutte le categorie esaminate, tranne che nei vitelli di un allevamento intensivo modello, dove erano state prese tutte le precauzioni tecniche e strutturali per proteggerli durante l'inverno. Questo dato conferma il fatto che le basse temperature, comprese quelle non eccessivamente rigide dei territori del sud Italia, costituiscono un fattore di stress per la specie.
Oltre allo studio per definire i valori di riferimento dei parametri finora indagati, sono in corso gli approfondimenti relativi alla variabilità dei livelli di immunità innata in presenza di evidenti fattori stressogeni acuti e cronici, nonché di malattia conclamata, al fine di fornire un ulteriore strumento valutativo del benessere della specie bufalina, attualmente in espansione sul territorio italiano.

Conclusioni

Al fine di proteggere la specie bufalina dalla progressiva intensificazione dell'allevamento, non sempre rispettosa delle esigenze della specie, è auspicabile la realizzazione di uno schema standard di monitoraggio, basato su rilievi zootecnici strutturali, di produttività e riproduzione, di comportamento e di laboratorio, con lo scopo di tutelare il benessere di una specie in espansione, nonchè di migliorare la percezione da parte del consumatore della qualità dell'intera filiera produttiva.

EFFECT OF AUTONOMIC NERVOUS SYSTEM DYSFUNCTION ON SUDDEN DEATH IN ISCHEMIC PATIENTS WITH ANGINAL SYNDROME DIED DURING ELECTROCARDIOGRAPHIC MONITORING IN IC

Lettieri B. Delle Donne D.

Abstract

Objectives. The aim of this study was to investigate the role of sympathovagal imbalance in patients with " ischemic" sudden death (arrhythmic death preceded by ST segment shift).

Background. Although heart rate variability is a powerful tool for risk stratification after myocardial infarction, the mechanism precipitating sudden death is poorly known.

Methods. We analyzed the tapes of 10 patients who had ischemic sudden death during ECG Holter monitoring. Thirty patients with angina and transient myocardial ischemia during Holter monitoring served as control subjects. Arrhythmias, ST segment changes and heart rate variability were analyzed by a computerized interactive Holter system.

Results. In eight patients the sudden death was induced by ventricular fibrillation; in two by atrioventricular block followed by sinus arrest. All ten patients showed ST segment shift. ST depression (maximal change 0,54 ± 0,16 mV) occurred in six and ST elevation (maximal change 0,65 ± 0,24 mV) in four. The standard deviation of normal RR intervals (SDNN) was 92 ± 30 ms during total Holter monitoring period vs 70 ± 10 ms and 46 ± 8 ms in epoch 1 and epoch 2 respectively. The SDNN was lower before the occurrence of ischemic sudden death: 54 ± 12 ms ($p< 0,005$) in epoch 3 and 26 ± 5 ($p<0,005$) in epoch 4 (i.e. 5 min before the onset of fatal ST segment shift). In controls the SDNN was 108 ± 30 ms during total Holter monitoring period, whereas is measured 58 ± 28 ms 5 min before the most significant episode of ST shift vs 26 ± 5 in the group with sudden death.

Conclusions. Sympathovagal imbalance, as detected by a marked decrease in heart rate variability, is present in the period (5 min) immediately preceding the onset of the ST shift precipitating ischemic sudden death. These findings suggest that transient autonomic dysfunction may facilitate, during acute myocardial ischemia, fatal arrhythmias precipitating in sudden death.

Key words: ischemic sudden death, ECG Holter monitoring, heart rate variability, standard deviation of normal RR intervals(SDNN), ST segment shift, arrhythmias.

Introduction

The sudden death is the most rilevant adverse event in patients with ischemic heart disease (1,2,3,4). More than two thirds of these deaths can be attributed to the occurrence of malignant ventricular arrhythmias (5,6). The current phatophisiological knowledges are not able to identify the patients at high risk eligible for an antiarrhythmic pharmacological treatment able to improve the survival of these patients. Data from experimental research indicate that both acute myocardial ischemia(5,6,7) and autonomic nervous system dysfunction (8) may induce fatal arrhythmias. Previous studies have found that low heart rate variability is due to autonomic nervous system dysfunction with high sympathetic activity and/or concomitant low vagal activity (9,10). However, the mechanism by which sympathovagal imbalance may precipitate sudden death in humans is not clear (11,12,13). The best source of information to evaluate the correlation between sympathovagal imbalance and sudden death comes from the tapes of patients who died during ambulatory electrocardiography Holter monitoring (14,15,16,17).

The aim of this study was to investigate the correlation between ischemic sudden death (arrhythmic death preceded by ST segment shift) and autonomic nervous system activity in patients died during Holter monitoring.

Materials and Methods

We studied 12 patients with anginal syndrome and ischemic sudden death during Holter monitoring in our Intensive Unit Care (11). The sudden death was defined "ischemic" when the fatal arrhythmia was preceded by significant transient ST segment shift. Thirty patients, gender and age-matched, with angina and transient myocardial ischemia, but no life-threatening ventricular arrhythmias (Lown class<4) during 24-h Holter monitoring, served as control subjects. All Holter tapes were performed by our Department of Anesthesiological Sciences and Critical Care between January 1996 December 2005. Tapes were analyzed by a computer-assisted Holter system for heart rate variability (Marquette Electronics Inc). All arrhythmic events and ST segment trends were analyzed to identify fatal arrhythmia and transient ST segment changes suggestive of myocardial ischemia (ST shift >0,15 mV lasting >2 min). Time domain measurement of heart rate variability indexes were assessed by an automatic program. Three-channel ECG recordings were used; artifacts, ectopic beats and period with significant ST segment changes were removed by RR calculations. Heart rate ranges was analyzed between 40 and 300 heats/min. The maximal allowable beat to variation was 20%.

Measurements were obtained by active analyses of 5 and 60 min time segments ("epochs"). All normal RR (NN) intervals and their standard deviations (SD) were used to calculate five variables strictly related to changes in sympathovagal balance (18):

-SDNN (standard deviation of NN interval) : the square root of the variance of successive QRS intervals. It reflects all the cyclic components responsible for variability and serves as a global marker of HRV, encompassing vagal and sympathetic influences (mean normal value > 140 msec).

-SDANN index: the average of mean SDs for 5 min segments

-pNN50 :the percent difference of successive normal beats differing by >50 ms

-rMSSD : the mean square root of the SD.

In patients with sudden death the mean value of two heart-rate variability indexes (SD of NN intervals and percent of NN > 50 ms), were measured as follows:

1) for the total Holter recording;
2) in the initial 1 hour (epoch 1), including the last 5 minutes (epoch 2) ;
3) 1 hour (epoch3), including the last 5 minutes (epoch 4), before the onset of ST segment shift, whether or not ST segment change led to sudden death.

The remaining variables, SDNN index, SDANN index and rMSSD were calculated in the overall 24-hours Holter recording and in epochs, 1 and 3.

In the control group, the SD of NN intervals and the percent of NN>50 msec, were measured during the overall 24-hours Holter recording and 1h and 5 min before each episode of the ST segment shift (epoch 3 and epoch 4 respectively).

Statistical analysis

Statistical analysis within each group was performed by the student paired t-tests. Comparison between the two groups was assessered by Mann-Whitney-Wilcox on rank sum test ; p values < 0,05 were considered significant.

Results

Patients with ischemic sudden death.

Twelve patients were included in the study: ten men and two women.

Two patients were excluded: one because taking verapamil and the other because under treatment with flecainide.

All patients underwent Holter monitoring in our Department of Anesthesiological Sciences and Critical Care. All patients had a history of angina pectoris (six patients were affected by unstable angina and four by chronic stable effort angina).

No patient had a history of diabetes or was taking antiarrhythmic drugs, including digoxin or a beta-blockers. The general clinical characteristics and the drug treatment of the patients with sudden death are shown in the table 1. The mean duration ± SD of ECG Holter recording was 14,3 ± 5 h (range 5 to 22 h).

All patients showed ventricular ectopic beats during monitoring, only two patients had frequent (> 15 h) and complex (couplets) ventricular ectopic beats.
Sudden death was due to a ventricular fibrillation in eight patients (in one patient preceded by torsade de pointes in the other by sustained ventricular tachycardia), on the others two patients the sudden death was due to an advanced atrioventricular block followed by a sinus arrest. All patients reported chest pain before dying. All patients exhibited ST segment shift suggesting for ischemia during ECG monitoring (ST depression in six and ST elevation in four). The mean duration of fatal ST shift episodes was 52 ± 30 min (range 12-105).
The mean heart rate at the onset of ST shift was 86 ±12 beats/min, vs 76± 14 heats/min, during overall monitoring (p = NS).
In four patients seven additional ischemic episodes occurred during ECG monitoring ≥1 h before the onset of ischemic sudden death.
Such ST shifts (lasting 48±27 min ; 0,32±0,8 mV) were defined nonfatal episodes of transient myocardial ischemia and were used for analytic purposes. Tab 2 shows Holter data.
Control group
The control group comprised 30 patients (20 men and 10 women; mean age 68 ± 8 yr) 18 with unstable angina and 12 with stable angina. During Holter monitoring none was taking antiarrhythmic drugs, including digoxin or beta blockers. Fourteen patients were being treated with nitrates and sixteen with calcium channel blockers. The percent of patients taking these antianginal medications was similar to that observed in the group with sudden death. All patients showed ST segment changes suggestive for myocardial ischemia.The chest pain was associated with ST segment shift in 22 of the 30 episodes. Eighteen episodes of ST segment depression (maximum 0,38 ± 0,15 mV) and twelve of ST elevation (0,46 ± 0,30 mV) were registered. The mean duration of such episodes was 42 ± 18 min range 8-98 min). The mean heart rate at the onset of ST shift was 88 ± 16 beats/min whereas the it was 70 ± 7 beats/min during 24-h Holter monitoring (p<0,005).
Heart rate variability analysis in the patients with ischemic sudden death.
The mean RR interval in the patients of the group with sudden death was 773 ± 72 during the overall ECG monitoring period. Time domain measurements of heart rate variability were as follows:
The total SD of NN intervals was 92 ± 30 ms vs 70 ± 10 and 46 ± 8 ms in the initial epochs 1 and 2 respectively. The SD of NN intervals was lower in epoch 3: 54 ± 12 (p<0,005) and in epoch 4 (i.e. 5 min before the onset of the fatal ST segment shift): 26 ± 5 (p<0,005) (tab.3). Furthermore, the lowest value of SD of NN intervals, in the total Holter recording period, was not statistically different from the epoch 4 measurements: 23 ± 9 vs 26 ± 5, p= NS.
Values for the remaining variables of sympathovagal imbalance (tab.3), referring to overall and 1-h period, gave similar results.
The parasympathetic variables of heart rate variability were slightly lower before the ST shift leading the sudden death than in the initial time segments. The percent of NN>50ms was 9,1 ± 6,8% in epoch 1 vs 8,8 ± 6,5 % in epoch 3, p=NS; whereas it was 9,6 ± 7 % in epoch 2 vs 6,2 ± 4,2 in epoch 4 (p<0,001). Similarly, no statistically significant difference between the root mean square of SD (rMSSD) in epoch 1 and 3 (33 ± 10 vs 31 ± 9; p=NS) was found. The two patients with bradyarrhythmic death showed persistent and markedly low values of percent of NN>50 ms during the overall ECG monitoring period (range 0 to 2,5 %).
Heart rate variability analysis in the patients of the control group
In all patients of the control group the heart rate variability was analysed before 30 episodes of ST shift. The mean SD values of NN intervals in patients with ischemic sudden death and in controls are depicted in fig. 1. The SD of NN intervals during 24 hr was 108 ± 30ms.The SD of intervals of NN in epoch 3 (1 h before the most significant episode of ST shift) was 68 ± 23 ms vs 65 ± 28 ms in epoch 4 (i.e. 5 min before the most significant ST shift episode); p=NS.
Parasympathetic variables (percent of NN>50 ms), during overall monitoring, were not

significantly different from those obtained in epoch 3 and 4 (6,8 ± 5,4 % vs 7,2 ± 5,5 and vs 5,4 ± 6,8%).
The total SD of NN intervals is similar in the patients with sudden death and controls, whereas the analysis of epoch 4 (i.e. 5 min before the ischemic episode) shows a significant statistically difference between the two groups: 30 ± 5 in the patients with sudden death vs 65 ± 28 in the control group; $p<0,001$.
In the 4 patients with sudden death who had 7 additional nonfatal ischemic episodes, the total SDNN was not significantly different from those found in the patients with sudden death. In the same patients the measurements 5 minute before the onset of ST changes differed significantly from those of epoch 4 (68 ± 20 vs 30 ± 12; $p<0,001$).
The values of SD of NN intervals of the two groups of patients are depicted in the fig.1.

Discussion

In this study the balance between sympathetic and vagal activities has been evaluated by means of heart rate variability analysis.
Many studies demonstrated that both a reduction of vagal output and an increase in adrenergic drive may be deleterious and lead to ventricular arrhytmogenesis (19,20). The relationship between increased heart rate, expressing low vagal output and increased sympathetic tone, and increased risk of death was observed in GISSI-2 study: in 8915 patients with acute myocardial infarction, discharge heart rate was an independent predictor of total mortality (21). In the ATRAMI study (Autonomic Tone and Reflexes After Myocardial Infarction) both heart rate variability and baroreflex sensitivity were determined in 1284 patients in the first month after acute myocardial infarction (22). In this trial, a SDNN<70 msec was associated with increase of death of 3.2. In this study it was also demonstrated that the marker of vagal dysfunction such as rMSSD is an important arrhythmogenetic factor.
The results of our study suggest that a decrease in heart rate variability in the short time period (5 min) preceded ischemic sudden death in patient with an anginal syndrome undergoing Holter monitoring. A decrease of SDNN was found before all ischemic episodes, in both the sudden death and control groups. Sympathovagal imbalance, as expressed by SD of NN intervals, shows dramatic changes before the ST shift leading to sudden death, compared with findings in patients with transient myocardial ischemica as well but without death or malignant arrhythmias.
In our study all patients who died suddenly had an SD of NN intervals value <35 msec 5 min before the onset of fatal ischemic episode whereas all patient of control group had higher values. The analysis in four patients with sudden death of seven non fatal ischemic episodes with values of SD of NN intervals > 60msec, confirms the strict relation between this parameter and the ischemic episodes related to sudden death.
All the fatal ventricular tachyarrhytmias episodes occurred in patients with ST depression whereas the two patients with bradyarrhytmias showed an ST elevation.
A relation between ST shifts and type of arrhythmias is uncertain.
In this study the two patients with bradyarrhytmias showed persistently low levels of percent of NN>50 msec, whereas the patients with sudden death showed a dramatic decrease in this index before fatal ST shift. These findings suggest that different patterns of sympathovagal imbalance may precipitate different manifestations of ischemic-induced arrhythmic sudden death.
Although the concomitance of multiple pathogenetic factors (15,23) seems to be mandatory for precipitation of sudden death, the autonomic nervous system activity has been suggested to be an independent risk factor for sudden death (24).
Furthermore, the low values of SD of NN intervals observed in the present study before ischemic sudden death (< 35 msec) was similar to those found in high risk patients, whereas the value of total SD of NN intervals observed in our study (86 msec) is similar to that found in patients with coronary artery disease. This finding suggests that sympathovagal imbalance may have only a functional mechanism, because patients with ischemic sudden death did not show any cardiovascular disorders able to reduce heart rate variability, such as recent infarction, heart failure

or diabetes (25). Furthermore both patients with sudden death, and control subjects were taking cardioactive drugs, such as calcium channel blockes or nitrates,that have no or little effect on heart rate variability (23,26). Thus, the marked decrease in SD of NN intervals occurring in the 5 min before fatal ST segment changes, found in our study, has pathogenetic implications,suggesting that transient myocardial ischemia may trigger malignant arrhythmias when superimposed on transient autonomic dysfunction.

In conclusion our data confirm the role of sympathovagal imbalance in patients with sudden death and suggest that measurement of autonomic nervous system activity may play an important role in evaluation of the risk of sudden death in patients with transient myocardial ischemia.

Ambulatorio di Ossigeno-Ozonoterapia, Direttore Biagio Lettieri

Introduction

The Health Ministry has notified, by ministerial notes of 1992 and 1996, the indications and action mechanisms of O_2-O_3 therapy.

There is already extensive international literature on the ozone effectiveness as a hemorhreological drug [1-15], a body protector [11-14] and as analgesic medication.

In the clinic we have improved and stabilized ingravescent diseases between 60% -80% of cases. he laboratory provided us with interesting experimental data to understand in part the ozone therapeutic efficacy as analgesic and anti-inflammatory drug, when administered. Ozone gas is naturally present in various layers of the atmosphere and it will give many important effects of both physical-chemical and biochemical. First of all the power absorption of UV solar rays make it a atmosphere key component for organic life on our planet.

At the biochemical level, the action takes place primarily on ozone coenzymes and organic substances, and later involves the metabolism three basic lines: lipids, carbohydrates and proteins. These particular interactions with the ozone metabolism cause various reactions in the blood, with different effects on both the corpuscular elements and on the plasma.

Particularly important are the effects on erythrocytes, including:

- peroxide (increased negative charge in the membrane)
- shortening of the lipid chains (this allows the relaxation of the membrane)
- increased production of 2-3 diphosphoglycerate (acceleration of glycolysis).

Just this substance have significant importance for the ozone therapy effects in vascular disease of both man and animal, because it increases the supply of oxygen to tissues by Hb.

Discussion

Therefore considering the anti-inflammatory and analgesic action of O_2-O_3 mixture two studies have highlighted the use of O_2-O_3 mixture as:

- cardio-protective drug in ischemia reperfusion infarct;
- analgesic and anti-inflammatory drug in the treatment of neuropathic pain.

Regarding the first point, in a study on rats, was given the O_2-O_3 mixture on myocardial tissue damage due to an ischemic event. Rats treated with the O_2-O_3 mixture showed significant cardioprotection compared with control rats.

This effect was associated with a decrease in tissue markers of oxidative stress (nitrotyrosine) (figura 1), inflammation (CD68) and immune response (CD4 and CD8) in the rats infarcted myocardium treated with the O_2-O_3 mixture (figura 2). These data indicate that tissue damage associated to biochemical ischemia/reperfusion myocardium, can be countered by an acute pre-treatment with O_3 .

Regarding the second point of considerable importance for the treatment of pain in humans and animals, is the action that ozone exerts on both the mediators and the program of cell death or apoptosis.

Experimental data show that ozone is able to act, limiting the action and the same synthesis, on enzymes which the caspases.

The caspases known are 13. Those we studied are 4: Caspase-1, caspase-12, caspase-8 and caspase-3.

The first two (caspase-1 and caspase-12) involved in complex inflammasoma formation and are

responsible for the release of pro-inflammatory cytokines. Indeed, it was found that after exposure to pathogenic noxa activates a series of mediators of cellular damage that induce synthesis and release of caspases,
which promote the synthesis and release of pro-inflammatory cytokines such as IL-1b, IL-10, IL-18, etc... (Figura 3). As noted in studies conducted in mice subjected to sciatic nerve ligation, the pain causes gene over-Expression and then synthesis of mediators such
IL-1, pro-inflammatory cytokine, mainly in the cortex and spinal cord, through the synthesis of caspase-1.
Ozone has the ability to inhibit the release of caspase-1 and 12 through its immunomodulatory action also states also from studies of gene amplification (RT-PCR), which notes that the drug reduces the synthesis of caspase -1, TNF-R, IL-1B and 10 (Figura 4).
Furthermore, another important function of ozone is linked to inhibition of the mechanism of cell death (apoptosis) mediated by caspase-8 and caspase-3, which is amplified during chronic pain, both cortical bone marrow for halogenated continuous stimulation (Figura 5).
It was pointed out that during the O_2-O_3 treatment, a reduction in both cortex and spinal cord of caspases involved in this process.

Conclusion

Based on what was said and shown by various studies and results in human trials, we can say that ozone, having both anti-inflammatory properties that inhibit the mechanism of cell death and realizing from the clinical point of view a reduction of painful symptoms in humans, is a drug applicable in veterinary medicine, being cheap, without all those side effects associated with the use of various molecules and anti-inflammatory analgesic marketing, both in man and animal. From this it requires a greater encouragement to continue research and to determine an upper extension of the therapeutic applications of ozone in animals.

Introduction

Neuropathic pain is defined as pain initiated or caused by a primary lesion or dysfunction in the nervous system [1, 2]. Due to its very complex nature, neuropathic pain does not respond to currently-used analgesic drugs, such as antiepileptic drugs, opioids, antidepressant agents.

Peripheral neuropathy triggers several biomolecular events propagating to the spinal cord and brain, where they are integrated and processed by limbic and cortical areas [3]. Several pre-frontal cortical areas are part of the brain network for pain [4]. Recent evidence suggests cortical neuroplastic changes including genes activation of neurotrophic factors in chronic pain conditions [5].

The caspase family comprises thus far 13 different cysteine proteases that are mainly involved in the apoptotic pathways. Among them, caspase-1 is less involved in the apoptotic cascade, but it is prominent in inflammation because of its pivotal role in regulating the cellular export of pro-inflammatory cytokines such as IL-1β and IL-18. These enzymes regulate the inflammatory processing of CNS diseases, including spinal cord inflammation and neuropathic and chronic inflammatory pain [6].

Ozone is a gas constituting an ozone and oxygen mixture. It has a great oxidative power and it has been used in medicine for the treatment of several illnesses with a wide spectrum. Ozone has been proposed as an antioxidant enzyme activator, immunomodulator, and cellular metabolic activator [7]. Several experimental and clinical evidences have shown advantageous effects of oxygen/ozone therapy in several pathologies characterized by a cellular oxidative and inflammatory response, including renal injury, cardiopathy, atherosclerosis and septic shock [8]. Indeed, ozone therapy shows long-term anti-inflammatory effects and reduces pro-inflammatory factors without toxicity or serious side effects.

In this study, we have studied whether a single subcutaneous administration of the O_3/O_2 mixture two days after sciatic nerve injury was anti-allodynic and anti-hyperalgesic in the first phase of neuropathic pain (i.e. 7 days post-injury). In addition, we have addressed the issue of whether O_3/O_2 mixture treatment was capable to reduce the spinal and supra-spinal SNI-over-expression of pro-inflammatory genes.

Materials and Methods

Animals. Male C57BL/6N mice (35–40 g) were housed 3 per cage under controlled illumination (12-h light/12-h dark cycle; light on 06:00 h) and environmental conditions (room temperature 20–22 ◦C, humidity 55–60%) for at least 1 week before the commencement of experiments. Mouse chow and tap water were available *ad libitum*. The experimental procedures were approved by the Animal Ethics Committee of the Second University of Naples. Animal care was in compliance with the IASP and European Community (E.C. L358/1 18/12/86) guidelines on the use and protection of animals in experimental research. All efforts were made to minimise animal suffering and to reduce the number of animals used. Ozone/oxygen mixture was generated by Multiossigen Medical-93 (Multitech, Milan, Italy). Ozone obtained from medicinal grade oxygen was used immediately.

*Treatment.*Mice were grouped (n=5) as follows:

(a) Naıve mice; (b) Sham mice; (c) Sham-operated mice treated with a single administration of O_2/O_3 gas mixture (around 180 μg/kg s.c.); (d) SNI mice; (e) SNI mice treated with a single administration of O_2/O_3 gas mixture (around 180 μg/kg s.c.).

Sham operated and SNI mice were assessed for the development of thermal hyperalgesia and

mechanical allodynia before any other examination. Behavioural testing was performed before surgery to establish a baseline for comparison with post-surgical values. Behavioural analysis was performed 1 h after the last injection of O_2/O_3 gas mixture. Ozone dose and administration procedure were consistent with concentration and timing of oxygen/ozone treatment applied in ozone-therapy in human neurosurgical procedures [9].

Spared nerve injury. Mononeuropathy was induced according to the method of Bourquin and Decosterd [10]. Mice were anaesthetized with sodium pentobarbital (60 mg/kg i.p.). The sciatic nerve was exposed at mid-thigh level distal to the trifurcation and freed of connective tissue; the three peripheral branches (sural, common peroneal, and tibial nerves) of the sciatic nerve were exposed without stretching nerve structures. Both tibial and common peroneal nerves were ligated and transacted together. The sham procedure consisted of the same surgery without ligation and transection of the nerves.

Nociceptive behaviour. Thermal hyperalgesia was evaluated by using a Plantar Test Apparatus (Ugo Basile, Varese, Italy). On the day of the experiment each animal was placed in a plastic cage (22cm x 17cm x 14cm; length x width x height) with a glass floor. After a 60 min habituation period, the plantar surface of the hind paw was exposed to a beam of radiant heat through the glass floor. The paw withdrawal latency (PWL) was automatically displayed to the nearest 0.1 sec; the cut-off time was 20 sec in order to prevent tissue damage.

Mechanical allodynia was measured by using Dynamic Plantar Anesthesiometer (Ugo Basile, Varese, Italy). Mice were adapted to the testing environment before any measurements were taken. After that, the mechanical stimulus was delivered to the plantar surface of the hindpaw of the mouse from below the floor of the test chamber by an automated testing device. A steel rod (2 mm) was pushed with electronical ascending force (0-30 g in 10 sec). When the animal withdrawn its hindpaw, the mechanical stimulus was automatically withdrawn and the force recorded to the nearest 0.1 g. Nociceptive responses for thermal and mechanical sensitivity were expressed as thermal paw withdrawal latency (PWL) in seconds and mechanical paw withdrawal threshold (PWT) in grams.

Each mouse served as its own control, the responses being measured both before and after surgical procedures. PWL and PWT were quantified by an observer blinded to the treatment.

RNA extraction and RT-PCR. Total RNA was extracted from homogenized pre-frontal cortex and spinal cord using an RNA Tri-Reagent (Molecular Research Center Inc., Cincinnati, OH) according to the manufacturer's protocol. The extracted RNA was subjected to *DNase* I treatment at 37°C for 30 min. The total RNA concentration was determined by UV spectrophotometer. The mRNA levels of the genes under analysis were measured by RT-PCR amplification, as previously reported [11]. A semiquantitative analysis of mRNA levels was carried out by the "Gel Doc 2000 UV System" (Bio-Rad, Hercules, CA). The measured mRNA levels were normalised with respect to hypoxanthine-guanine phosphoribosyltransferase (*HPRT*), chosen as housekeeping gene. The *HPRT* gene expression did not change in several experimental conditions. To our knowledge there is no molecular evidence for variation in HPRT mRNA-levels in SNI neuropathic pain model [6]. The gene expression values were expressed as arbitrary units ± S.E.M. Amplification of genes of interest and *HPRT* were performed simultaneously.

Statistical Analysis. Behavioural data are represented as means ± S.E.M. ANOVA, followed by Student–Neuman–Keuls *post hoc* test were used to determine the statistical significance among groups. Molecular and biochemical data are shown as means ± S.E.M., ANOVA, followed by Student–Neuman–Keuls *post hoc* test, were used to determine the statistical significance among groups. $P < 0.05$ was considered statistically significant.

RESULTS

Ozone prevents the development of mechanical allodynia and thermal hyperalgesia

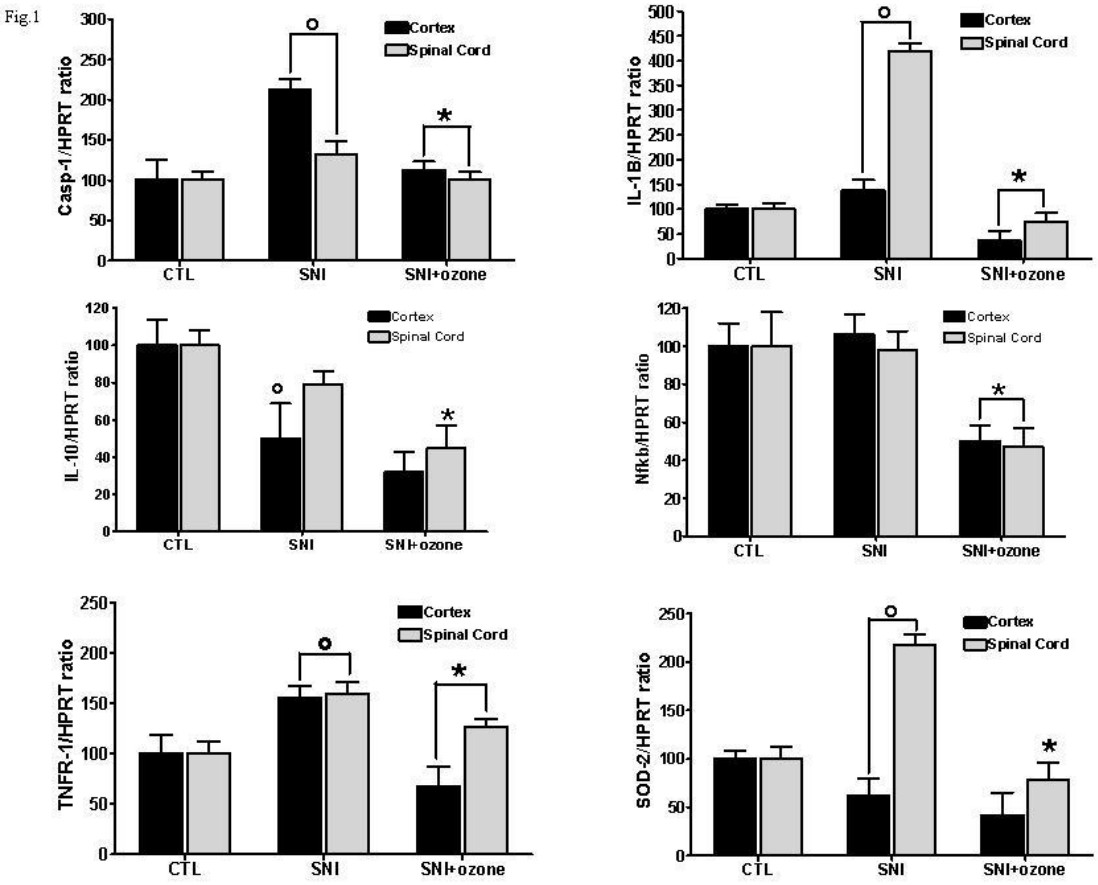
In naïve mice, the behavioural change of mechanical allodynia and thermal hyperalgesia did not significantly undergo modification during analgesimeter registration. SNI of the sciatic nerve resulted in significant decrease in PWT and in PWL in the ipsilateral side of mice 7 days after

surgery. The increased sensitivity in the SNI sides was not present on the contralateral sides. A single administration of ozone performed 2 days after SNI surgery, was effective in preventing the appearance of mechanical allodynia and thermal hyperlagesia at 7 days post-SNI.

Ozone prevents the over-expression of pro-inflammatory genes

The semiquantitative analysis of mRNA levels measured by RT-PCR amplification in the pre-frontal cortex and in spinal cord of mice, showed an increase in the pro-inflammatory *caspase-1, IL-1β, IL-10, NF-kβ, TNF-R1 and SOD2* genes 7 days after the SNI of the sciatic nerve. Ozone inhibited the gene over-expression in 7 days SNI pre-frontal cortex and in spinal cord (Fig. 1).

Figure 1. The mRNA levels (mean ± SE) of the genes under analysis measured by RT-PCR amplification were reported. °p<0.05 *vs* the corresponding naïve mice, *p<0.05 *vs* the SNI ozone untreated mice, as analysed by ANOVA, followed by Student-Neuman-Keuls test. Legend: CTL control mice; SNI neuropathic mice; SNI+ozone neuropathic mice treated with ozone.



Discussion

The present study offers evidence indicating that the pro-inflammatory *caspase-1, IL-1β, IL-10, NF-kβ, TNF-R1 and SOD2* gene expressions were significantly increased in the pre-frontal cortex and in spinal cord seven days after SNI in the mouse.

Our data indicate that peripheral nerve injury activates a neuroinflammatory-like process in the central structures controlling pain processing. Moreover, treatment with ozone has been clinically effective in decrease the behaviour indication of the neuropathic pain. Ozone was able to inhibit the transcription of the genes involved in the cellular stress and inflammation and reduce pain-like behaviours.

Collectively, these preliminary data indicate that ozone can be an effective practice for preventing the development of neuropathic pain through complex as yet unexplored mechanisms and, among these, through the modulation of specific pro-inflammatory genes in the central nervous system.

ANALGESIC EFFECTS OF OXYGEN/OZONE THERAPY IN ARTERIAL OBSTRUCTIVE PATHOLOGY.

Mascolo Luigi, Luongo Margherita

On the basis of Fontaine classification, the arterial vascular insufficiency triggers "claudicatio intermittens" due to ischemia/hypoxia during walking.
A study published on Circulation (2006; 113: 463-654) highlighted that drugs or factors of Level of Evidence A in the peripheral arterial disease are: exercise activity, cilostazol (in Italy not yet disposable) and pentoxifyline. According to this study, other drugs (i.e. beraprost, iloprost, l-arginine, propionyl-l-carnitine) did not show a definite effectiveness. The vasculopathy is able to trigger peripheral pain.
Ozone therapy has been shown to have therapeutic efficacy in positively change the emo-reologici factors conditioning peripheral oxygen reperfusion. Clinic therapy has confirmed this hypothesis.
We report our experience in a vasculopathic chronic patient group of Fontaine level 3 and with peripheral ulcer, has been administrated one cycle of systemic O2-O3 mixture treatment.
O2-O3 mixture treatment was able to decrease pain in resting state, as well as to increase free movement in these patients.
These results indicate that O2-O3 mixture could be an optimal treatment in the arterial vascular insufficiency care.

In the treatment of pain and particularly of the moderate and severe chronic pain, opioids remain one of the most effective and used therapies. However too often patients achieve little or no pain relief due to the number of side effects that limit their intake. The OPIAD, i.e. the opioid induced androgen deficiency is one of the mostly constant syndrome. That exposure to opioids decreases gonadal hormones in humans, as well as in experimental animals treated with different opioids, is a quite aknowledge fact looking at the several paper present in the literature (1-3). Several hypothesis have been suggested to explain such a possible pathogenesis , one of these considers the inhibition by opioids of the releasing factors secretion at hypothalamic level, another a direct inhibitory action at the pituitary level via specific binding sites on the gonadotrophs, however other hypothesis were tested. We present in this review a series of experiments carried out in different patients population, in experimental animals and in vitro in which the study of hypothalamo-pituitary-adrenal/hypothalamo/pituitary/gonadal related hormones appears to significantly respond to the different opioid actions.

Effect of i.t. morphine administration in men and women subjects

To evaluate the immediate effects of morphine spinal administration on steroid hormones and their time course we considered male and female patients implanted with an i.t. catheter, due to a persistent severe pain. The morphine intratecal daily dose was 0.9 mg/die and the overall administration time was 15 days. The following hormones were considered: LH, FSH, Testosterone, Free Testosterone, Cortisol. Blood was collected and analysed on Day 0, 1, 2, 15 (last day of administration) and 16 (the day after the withdrawal of morphine). In females and males, in fact, total testosterone and free testosterone blood levels as well as cortisol resulted to be greatly reduced with respect to the basal levels since Day 1 to Day 15 and completely recovered 24 hrs after the end of treatment (16th day). By contrast gonadotropins tended to minimally increase with respect the basal levels in males and to decrease in females. These findings clearly show that the administration of morphine, also via i.t., immediately affects gonadal hormones and cortisol , independently from the gender. Indeed, whereas in males a hypothalamo/pituitary axes inhibition has to be excluded due to the lack of gonadotropin decrement, in females a hypothalamo-pituitary involvement would be considered due to the decrease, even if small, of gonadotropins levels . Thus in interpreting the testosterone decrement in males a direct action of opioids on testis and/or an increase in testosterone metabolism has to be hypothesized.

Effect of the longlasting administration of transdermal Buprenorphine in males and females subjects

Male and female subjects undergoing buprenorphine transdermal intake (35 mcg/ h every 72 hrs) because of an acute/persistent pain were included in the study whose main aim was observing the modifications on HPG and HPA axes. Estradiol, Total Testosterone, Free Testosterone, DHT, Cortisol and SHBG plasma levels were evaluated, at basal level, and after 1, 3 and 6 months of therapy. During the observation period in females all hormones showed various slight changes that did not become significant except for total testosterone that resulted *increased* at 3 months. In males no significant difference was observed for all hormones except for free testosterone that appeared to be lowered after 3 months. In both sexes the HPA axis was *not* inhibited since cortisol progressively increased during treatment. SHBG is a rarely measured protein, it indicates the possibility of testosterone to be transported in the blood. In the present study its level doesn't change significantly in both sexes. In the present study its efficacy (buprenorphine: μ partial agonist and κ antagonist) with different characteristics with respect morphine (μ and κ agonist), showed

different effects, indeed the deficiency of the androgens in the blood is not present. This means that buprenorphine therapy may be carried out also for several months whithout falling in the hypogonadic conditions induced by morphine.

Effect of surgical analgesia by i.v. opioid administration in men

In the present study we measured the blood level of testosterone and estradiol in a sample of males patients who were submitted to an intervention to evaluate the modifications of these hormones in such a particular condition. It clearly appears that after the procedure the testosterone levels are very low, particularly when morphine is implemented with fentanyl. In addition in these patients also estradiol resulted to be lowered by treatment. In particular men treated only with morphine for the management of transvescical prostateadenectomia showed testosterone levels to be significantly reduced after 24 hrs, to completely recover three days later.

Effect of sc morphine administration in plasma and brain testosterone levels in male and female rats

Male and female rats were s.c. injected with morphine to study the effects of this opoid in testosterone plasma and brain levels. Blood and brain tissues were collected after 4 hours. It clearly appears that a decrement of testosterone has been observed in the blood of both female and male rats. In the brain testosterone was importantly decreased in males while in the female brain testosterone didn't reach detectable levels also in the saline treated animals.

Effect of morphine on testosterone levels in glia cells

A series of experiments were carried out to verify whether rat C6 glioma cells testosterone content was affected by morphine administration and whether this effect could be modified by the addition to culture medium of drugs interfering with testosterone degradation by acting on different enzymes: anastrazole or finasteride. We measured aromatase activity in pools of cells treated with ANA, morphine (10 μM) and the association of these two substances, versus control. Testosterone was measurable in the glioma cells and its level was strongly reduced by morphine addition in a dose dependent way. In other groups of glia cells the addition of anastrozole and finasteride differently affected testosterone concentration. With respect to controls, anastrazole significantly increased testosterone concentration, an effect completely abolished by the contemporary administration of morphine. In contrast finasteride did not change significantly the testosterone levels. Our data provide evidence that glial cells contain low, but detectable levels of testosterone and that morphine significantly decreases testosterone cellular levels.

DISCUSSION

All the experiments presented in this paper show the different ability of opioids to affect hormones. 4The hypopgonadism induced by morphine as well as the effect on neuronal content of testosterone have to be considered because although opioids remain the more important group of drugs commonly used in pain therapy, physicians need to be aware about all their long term consequences. Morphine and the other opioids, when given to treat pain, disrupt the physiological ratio between opioids and gonadal hormones, altering many of the several functions in which opioids and hormone act. This important interaction is probably involved in the different ability present in the two sexes to develop chronic pain (Aloisi and Bonifazi, 2006). In the second study, buprenorphine-treated subjects suffering acute persistent pain were studied for six months. Testosterone as well as estradiol is involved in wound healing through its action on tissue regeneration and immunity (i.e Engeland et al., 2008). Thus at present data are not clear on the effects of gonadal hormones on healing, but it is plausible to advance that morphine affect post-surgical patients not only by relieving their pain, but also changing their tissues repearing by healing via a temporary hypogonadism able to change the ratio among the immune and hormonal activation. In conclusion, Opioid therapy is mandatory in several pains, in particular in chronic pains. However its administration requires a detailed understanding of all mechanisms it affects including gonadal hormones metabolism. All the data we reported infact confirm in agreement with the findings described by other authors that morphine which is the mostly used compound significantly influence testosterone metabolism, also at glial cells level. Therefore the prescription

of an opoid treatment requires a paramount attention and awareness of these so involving side effects.

MULTIMODAL ANALGESIA FOR CHRONIC PAIN: RATIONALE AND FUTURE DIRECTIONS

Palomba R, Adiletta S, Candiello A, Pennimpede M, Bonaccia P, De Martino CJ

Chronic pain is a complex disease requiring multidimensional assessment and multimodal treatment. In chronic pain, dysregulation of one or many locations within the complex nociceptive and pain neural circuit leads to neuroplastic reorganization and increased spontaneous activity (spontaneous pain), as well as hyperresponsiveness to noxious (hyperalgesia) and non-noxious (allodynia) stimuli. The neuroanatomy of the nociceptive loop is comprised grossly of nerve endings of peripheral primary sensory ganglia, supraspinal nuclei, the thalamus, limbic and cerebral cortices, diencephalic processing and supraspinal descending modulatory control of the initial peripheral input at the spinal dorsal horn level.
Mechanisms regulating peripheral sensation play a critical role in the manifestation of chronic pain; several classes of primary sensory neurons with somata located among the dorsal root or cranial sensory ganglia have been described and respond to noxious and non-noxious mechanical (mechanoreceptors), thermal (thermoreceptors), or chemical (chemoreceptors) stimuli. The four broadly defined primary sensory afferent types include:

1. The largest caliber, heavily myelinated muscle spindle and Golgi tendon afferents responsible for signaling limb position and maintaining proprioceptive sense.
2. Large-caliber, heavily myelinated Aβ axons responsible for signaling highly discriminative mechanical stimuli transduction.
3. Small-caliber, lightly myelinated Aδ axons.
4. Smaller, unmyelinated C axons that form morphologically, simple free nerve endings (FNE)(1) that terminate within the epidermis, around the vasculature and all other skin appendages, as well as muscle, all visceral organs and bone.

A majority of FNE are believed to respond specifically to various noxious stimuli and are collectively termed “nociceptors”. As many as half of the Aδ and C axons are normally unresponsive to test stimuli used to functionally characterize sensory innervation by elettrophysiology. Many of these unresponsive axons have nociceptive characteristics and are believed to be driven only by severe tissue damage or prolonged experimentally induced pain, and are therefore referred to as “silent” nociceptors. Under acute tissue injury, quiescent nociceptive neurons may be activated by direct stimuli-mechanical, thermal or chemical, including such inflammatory cytokines as interleukin (IL)-1β and IL-6 released both immediately following injury and subsequently during tissue repair processes. Inflammatory cytokines thus activate nociceptive neurons, leading to the generation of pain and nocifensive behaviors that accompany tissue injury and repair.
Recent studies have dedemonstrated that neurons, keratinocytes (2)and vascular endothelial cells express common signaling pathways, suggesting a bidirectional communication between the nervous system and cells of the epidermis and vasculature. In particular, depending on the type, intensity and duration of a stimulus, epidermal keratinocytes release different combinations and proportions of excitatory and/or inhibitory ligands that influence neuronal activity. Studies have demostrated a role for β-endorphin, an endogenous opiate peptide produced by superficial keratinocytes, which may represent a tonic inhibitory tone on μ opiate receptors (μOR) expressing epidermal FNE. Loss of this tonic inhibitory mechanism within the keratinocytes would likely lead to hyperexcitability of the μOR- expressing fibers, heightened nociceptive-like responses to varied stimuli and potentially to chronic pain. In addiction to β-endorphin, keratinocytes release the purine nucleotide adenosine triphospate (ATP) in response to air contact and various mechanical stimuli; ATP likely contributes to the excitation of FNE axons through metabotropic G protein-coupled mechanisms (P2Y receptors) and through ionotropic direct ion-gated channels (P2X) that are present on small-caliber axons.(2)(3)

A loss of FNE may result in the disregulation of epidermal chemistry and inappropiate release of various ligands from keratinocytes, contributing to increased excitability of FNE.(3)(4)
Nociceptive primary afferent fibers use glutamate and neuropeptide transmitters to convey the status of the peripheral receptive field (5)(6); modulation of glutamate and its cognate receptor family are critical to nociceptive processing in the dorsal horn and likely have implications in neuropathic and chronic pain conditions. Additionally, primary peripheral nociceptive input is under tonic control by descending brain stem-level regulatory systems, using serotonin, norepinephrine and opioids as transimtters/modulators which can inhibit or facilitate nociceptive transmission in the spinal dorsal horn. Many drugs -including for example opiates, antidepressants and anticonvulsants- can influence the signaling of these descending systems and thereby achieve effective analgesia for patients with chronic pain. Additional alterations in signaling pathways involved in spinal-level nociceptive processing are not only limited to neural descending presynaptic control or to postsynaptic *N*-methyl-D-aspartic acid (NMDA) receptor modulation but also include glia(7): astrocytes can modulate synaptic function and release cytokines that sensitize the system and have been shown to discriminatively respond to active neurons, implying a bidirectional communication not previous appreciated.
Considering the fusion of central and peripheral mechanisms in the genesis of chronic pain, an important role for the successful treatment of patients suffered from chronic pain could be awarded to the use of palmitoylethanolamide (PEA) (8). PEA is not a drug but a nutritional element normally present in the human organism(9); it is a biological modulator supporting the control of the physiological tissue reactivity. PEA produces a down-modulation of mast cells- degranulation peripherally (10) and an activation of endocannabinoid receptor CB2 (CB2 –like) centrally.(11) (12)
In our study, we recruited 81 patients (age 28-75) with a diagnosis of low back pain,VAS>5;we administered opioids drugs (oxycodone) and drugs used for the neuropathic pain (antidepressants, anticonvulsants); furthermore, 41 of these 81 patients were treated with PEA (600 mg x 2/die 21 days then 600 mg/die 30 days). We valued the pain score with VAS at first examination, after 21 and 71 days; we considered effective the therapy when it caused a VAS>60% reduction , compared to the initial value. After 21 days, we verified a VAS> 60% reduction in 21 patients treated with PEA and 16 patients not treated with PEA; after 70 days, a VAS>60% reduction was in 32 patients treated with PEA and 22 patients not treated with PEA. Otherwise, in the group of patients treated with PEA, we observed a lower dose of drug used for the treatment of neuropathic pain (gabapentin, pregabalin, lamotrigine, duloxetine), compared to the group of patients not treated with PEA.

MECHANISMS UNDERLYING ANALGESIC TOLERANCE AND HYPERALGESIA TO OPIOIDS.

Palomba R., Pastore A., Adiletta S., Candiello A., Pennimpede M.,Viscardi D.

Opioid analgesics are effective in relieving chronic pain, but they have serious adverse effects, including development of tolerance and hyperalgesia.
The mechanisms underlying opioid tolerance are not fully understood, but appear to be comprised of two types of plasticity or counter-adaptation, at the cellular level and through neuronal circuits.
Current studies mostly emphasize the cellular adaptation mechanisms, which include altered gene expression,receptor down regulation and desensitization(due to phosphorylation and endocytosis).
However, the mechanisms underlying opioid tolerance and dependence are not always explained by cellular adaptation mechanisms alone. Recent studies have shown a counterbalance of opioid actions through an enhancement of synaptic activities between glutamate and NMDA receptor due to up-regulation of receptor and racemase to produce D-serine, an allosteric NMDA receptor agonist, and down-regulation of glutamate transporter.
The opioid-induced hyperalgesia,instead,is due to up regulation of NMDA receptor and to the apoptosys of neural cells that provide to the production of opioid receptors.
Our weapons to tolerance and hyperalgesia-opioid induced are the opioids ”switch”, the “multimodal analgesia” and new drugs based on the opioid assoiciation agonist-antagonist.

Summary
Pelvic Pain is a condition which occurs more in women (5% of the whole population) than men. As pelvic pain is related to several pathologies and determines a reduction of quality of life it needs an accurate evaluation. Many scales are used in order to measure pelvic pain; they are focused on several aspects of symptoms and a notable number of devices guarantee precision and objective evaluation.

Pain Evaluation

Chronic pelvic pain (CPP) is defined by the American College of Obstetricians and Gynecologists as "non-cyclic" pain of 6 or more months duration that localizes to the anatomic pelvis, anterior abdominal wall at or below the umbilicus, the lumbosacral back, or the buttocks and is of sufficient severity to cause functional disability or lead to medical care (1) put forward another definition of CPP, concerning an unpleasant, subjective, sensory experience confined to the pelvis. This would be generally associated to sensory, motor, affective and behavioral aspects. Pelvic pain can have both a nociceptive and neuropathic physiopathological component; in a chronic context it is not a diagnosis but a description of a clinical condition. In an acute context it may represent the fifth vital sign. This symptom affects women more frequently than men because of genetic, hormonal, anthropological, sociocultural, environmental aspects (2). Because of the strong relation between pain intensity and pain physiopathology, pain measurement awakened a lot of interest in the last 50 years. A suitable qualitative and quantitative pain analysis allows, indeed, a faster and more complete diagnosis which is particularly important in an emergency context. (3) states that scales developed for work for clinical disorders, such as CPP, need to demonstrate the qualities of content validity, test- retest reliability and responsiveness, among others. Pelvic pain measurement includes both verbal and instrumental methods to choose in relation to pain duration (acute or chronic), pathology (whose pain is the symptom), patient sex. The Pelvic Pain Assessment Form and the NIH- CPSI (National Institute of Health- Chronic Prostatic Symptom Index) Questionnaire are the only not instrumental sex- related methods to assess pelvic pain.

The Visual Analogue Scale (VAS), the Numerical Rating Scale (NRS), the Pain Diary are the most commonly one- dimensional scale used for pain measurement. In particular, VAS and NRS are considered to be superior to the First Behavioral Index (BI- 1) and to the Second Behavioral Index (BI- 2) in acute pelvic pain assessment because of their quickness and easiness of use. Besides, they do not underestimate pain (4).

The Mc Gill Pain Scale, the QUID, the Brief Pain Inventory (BPI), the Oswestry Disability Questionnaire, the Neuropathic Pain Scale, the LANSS Pain Scale, the Neuropathic Pain Symptoms Inventory represent the most successful multidimensional methods to assess pelvic pain. The Quality of Life Questionnaires, such as SF-36, SF-12, testing the effects of pain on the quality of life of the patient, can provide a good contribute to pelvic pain assessment too.

Women who suffer from chronic pelvic pain occur high risk of psychiatric disorders. By the form of quality of life (QoL) is evident how women with anxiety and depression refer a lower pain tolerance and pain causes a higher incidence of anxiety and depression. Hamilton Psychiatric Rating Scale for Depression and Hospital Anxiety and Depression Scale, are useful when they are associated with pathologies of psychiatric interest in patients with an historyof physical and/or sexual abuse.

Pelvic Pain may be evaluated using instrumental methods which offer an objective evaluation as

Algometry and Neurometer CPT-test.

The algometry supply an instrumental, suitable and effective measurement of pain sensitivity of pelvic muscles (internal algometer for women), abdominal muscles (pressure portable algometer) which has been demonstrated to be useful in both visceral and somatic pelvic pain (5). The pain threshold, given by the device, is defined as the intensity of pressure applied at which a patient reports a change in sensation from pressure to pain (6). Thermal algometry, giving the patients two fast trains of painful and thermal stimuli, can demonstrate a variation of thermal pain threshold due to central sensitization aspects likely associated to pelvic pain. In case of a neuropathic component in chronic pelvic pain the Neurometer CPT, (7) an electrodiagnostic device, can measure the current perception threshold (CPT) on small myelinated (A-delta) and unmyelinated (C) afferent nerve fibers giving out stimuli as graduated, alternating current. Nowadays physicians can have a lot of methods to assess pain quality, quantity, and diagnosis at their disposal. Their enjoyment allows to put the pain down to analytical characteristics, converting the symptom into a sign. To objectify a symptom strongly affected by cognitive-estimative, motivational-emotional, sensory-discriminative characteristics, actually represents a priority objective of pain research.

Pain measurement obtained through instrumental methods such as algometer, Neurometer CPT evaluation (8), electromyography deal with this new diagnostic trend. As concerning the non instrumental methods of pelvic pain assessment we support the construction validity, the content validity, the test- ratest reliability, the responsiveness, the easiness of administration, the comprehensibility to be some essential requirements. Neurometer, electrodiagnostic sensory nerve conduction threshold (sNCT) testing equipment is unmatched in its ability to painlessly and non-invasively provide a functional evaluation of sensory nerve integrity. Established normative painless Current Perception Threshold (CPT) values individually measure each the three 3 major sub-populations of sensory nerve fibers that compose the typical sensory nerve (Aβ, Aδ and C fibers). Neuroselectivity is achieved by using three different frequencies of an electrical sinewave stimulus (2000 Hz, 250 Hz and 5 Hz), taking advantage of this waveform's frequency dependent rate of depolarization. Large diameter fibers can generate action potentials in response to the rapid 2000 Hz stimulus but small fibers require several milliseconds of continuous depolarization (i.e. low frequency stimulation, e.g., 5 Hz), to reach threshold potential. Large fibers will generate action potentials to the 5 Hz stimulus, but not at physiologically significant rates. Additionally, the quantity of electrons or charge per depolarization of a 5 Hz sinewave (100 msec) is 400 times the charge and duration of a 2000 Hz sinewave depolarization (0.25 msec). Together, these factors result in the 2000 Hz stimulus selectively evoking physiologically significant large myelinated fiber responses and the 5 Hz stimulus selectively evoking physiologically significant unmyelinated fiber responses. The CPT evaluation permits the determination of neurological dysfunction from hyperesthesia/neuritis through hypoesthesia/neuropathy as well as monitoring the progression of nerve regeneration. The sNCT test reliably and accurately measures the function at any cutaneous site on the body including mucosal surfaces such as in the palate and the bladder. The Neurometer provides an objective automated non-invasive painless neuroselective evaluation of C fiber as well as Aδ and Aβ fiber functional integrity. Neurometer CPT test, furthermore, is successfully used after breast surgery in order to evaluate sensory dysfunction incidence after different surgical techniques and differences in perception in women with breast prosthesis and not (9). The electrodiagnostic measurement is conducted by the application of Electrodes positioned at the prescribed test site and held in place with tape. Honjo et al. conducted a trial, using neurometer for diagnosis of interstitial cystitis. Hann- Chorng Kuo et al. Underline the interest of literature in threshold study using Neurometer of sensory afferent fibers from the bladder in painful bladder syndrome, in interstitial cystitis and in Syndrome of unstable bladder.

Conclusion.

Pelvic pain can be evaluated by scales which offer an high level of reliability but they are related to the perception of the subjects. Considering the variety of symptoms, the number of evaluation scales and patients' subjective perception, it's difficult to be considered expert operators in this

subject.
The instrumental measurement allows a major precision in pain evaluation and in recognition of pathogenetic causes, as neuropathic causes which needs specific and focused treatment.

Background. The major psychoactive constituent of cannabis, Δ^9-tetrahydrocannabinol, affects pain sensation and emotional states in humans and laboratory animals by activating brain CB_1-type cannabinoid receptors. A primary endogenous ligand of these receptors is anandamide, the amide of arachidonic acid with ethanolamine. Anandamide is released in select regions of the brain and is deactivated through a two-step process consisting of transport into cells followed by intracellular hydrolysis by fatty-acid amide hydrolase (FAAH). Our lab has developed a potent and selective FAAH inhibitor, URB597, and investigated its pharmacological properties in live animals.
Methods. Behavioral analyses were conducted as described (Kathuria *et al.*, 2003; Gobbi *et al.;* 2005; LoVerme *et al.*, 2006; Bortolato *et al.*, 2007).
Results. URB597 inhibits FAAH activity *in vivo* with an ID50 of 0.15 mg/kg (ip, rat). At doses of 0.1-0.3 mg/kg (ip) URB597 exerts potent anxiolytic-like effects in the rat elevated plus maze and isolation-induced ultrasonic vocalization tests. At the same doses, URB597 elicits marked antidepressant-like effects in the mouse tail-suspension test, the rat forced-swim test and the chronic mild stress test. Moreover, URB597 reduces hyperalgesia and allodynia in a rat model of neuropathic pain (loose sciatic nerve ligature). These behavioral actions of URB597 (i) are accompanied by increases in the firing activity of serotonergic neurons in the dorsal raphe nucleus and noradrenergic neurons in the nucleus locus coeruleus; (ii) are prevented by the CB_1 antagonist rimonabant; and (iii) are maintained upon repeated URB597 administration. Unlike direct CB_1 agonists, URB597 does not exert rewarding effects in the conditioned place preference test or produce generalization to the discriminative effects of Δ^9-THC in rats. Finally, URB597 does not maintain self-administration or enhance Δ^9-THC self-administration in squirrel monkeys.
Discussion. Pharmacological blockade of anandamide deactivation produces anxiolytic-like, antidepressant-like and analgesic effects in rats and mice. These actions are not associated with other behavioral responses typical of direct-acting cannabinoid agonists – such as place preference or self-administration — and are accompanied by changes in serotonergic and noradrenergic transmission in select regions of the brain. These findings suggest that anandamide contributes to the regulation of pain and emotion, and that anandamide deactivation might be a target for novel analgesic, anxiolytic and antidepressant drugs.

N-Palmitoylethanolamide (PEA), the endogenous amide of palmitic acid and ethanolamine, belongs to the superfamily of *N*-acylethanolamides (NAEs), a class of lipid mediators. PEA exerts antinociceptive effects [1, 2], and inhibits peripheral inflammation and mast cell degranulation in rodents [3, 4].
Among the molecular mechanisms of PEA effects, we have previously demonstrated that its anti-inflammatory and analgesic effects were mediated by peroxisome-proliferator activated receptor alpha (PPAR-α). In fact PEA failed to exert these properties in PPAR-α knockout mice [5, 6, 7, 8, 9]. PEA interacts with this receptor with a potency comparable with that of the synthetic PPAR-α agonist GW7647, without activating the other PPAR isoforms, PPAR-β/δ or PPAR-γ [7, 8]. More recently, we have identified PPAR-α as the molecular target responsible for the analgesic effects of PEA [9].
Both PPAR-α and PPAR-γ receptor subtypes have been reported to regulate in vivo and in vitro inflammatory responses [10, 11, 12]. The first indication for a role of PPAR-α in modulating inflammation was demonstrated by that the ability of leukotriene B4, a potent chemotactic inflammatory eicosanoid, to bind PPAR-α and, in the last ten years, it has emerged that neurosteroids are strongly involved in several physiological cognitive and emotive functions of the CNS [13]. In the CNS, such as in periphery, the first and rate–limiting step in the biosynthesis of all steroid hormones is the conversion of insoluble cholesterol to soluble pregnanolone, which is accomplished by the cleavage of the cholesterol side chain, catalyzed by the mitochondrial cytochrome P450 enzyme, termed P450scc. This enzyme functions within the mitochondria [14] after delivery of cholesterol to the inner mitochondrial membrane due to steroidogenic acute regulatory protein (StAR) or peripheral benzodiazepine-type receptor (PBR) [15, 16, 17].
Very recently we have demonstated that several PEA effects are mediated in part by neurosteroids [18]. Neurosteroids are known to exert several rapid effects, including the modulation of hypnosis, through activation of $GABA_A$ receptors; these studies have been mainly conducted with the action of pregnanolone-like neuroactive steroid [19], and metyrapone, a blocker of the enzyme 11 β-hydroxylase, which is essential for the biosynthesis of corticosteroids [20]. Keller et al. [21] have shown that 5 α-reduced neurosteroids act on $GABA_A$, as well as PBR, modulating the GABA-induced Cl^- currents that result in neuron hyperpolarization. Among 5 α-reduced neuroactive steroids, the 3α-hydroxy-5α-pregnan-20-one (allopregnanolone, ALLO) displays anxiolytic, sedative, analgesic and anaesthetic properties [22], causing a great pharmacological interest.
The present study investigated the involvement of neurosteoid *de novo* synthesis in the mechanisms underlying PEA analgesic and anti-hyperalgesic effects in the formalin test and carrageenan-induced edema models in mice. Here, we report that PEA reduces nocifensive behaviours elicited in mice by intraplantar injection of formalin or carrageenan. The involvement of PPAR-α in the analgesic effect of PEA was evidenced in wild type mice, while was lacking in PPAR-α null mice subjected to formalin challenge. Moreover, PEA analgesic and anti-hyperalgesic effects partially disappeared treating mice with two inhibitors blocking the key steps of neurosteroid synthesis, aminogluthetimide and finasteride, implying that the antinociceptive effect is dependent on the *de novo* neurosteroid synthesis. In agreement with this data, the expression of StAR and P450scc, both

involved in neurosteroidogenesis was increased in spinal cord from PEA-treated mice subjected to both pain models. Accordingly, ALLO levels were in turn higher in spinal cord of PEA treated mice, as revealed by quantitative analysis using gas chromatography-mass spectrometry. Based on this evidence, this study brings novel arguments characterizing the role of PEA in physiological and pathological conditions, illustrating a novel aspect in PEA mechanism of action after PPAR-α activation, candidating PEA as a preferred drug in controlling pain perception.

Palmitoylethanolamide (PEA) regulates many pathophysiological processes, including pain perception, convulsions, and neurotoxicity (1-3). In the central nervous system (CNS), where PEA is present at high levels (4), increasing evidence points to its neuroprotective action: PEA concentration-dependently protected cultured mouse cerebellar granule cells from glutamate toxicity (3); it reduced histamine-induced cell death in hippocampal cultures (3) and enhanced microglial cell motility (5). The anti-inflammatory and analgesic effects of PEA were suggested to be mediated by peroxisome-proliferator activated receptor (PPAR)-a: in fact PEA failed to exert these properties in PPAR-a knockout mice (6). Very recently it has been demonstrated that PEA, through a PPAR-alpha-dependent mechanism, potentates pentobarbital-evoked hypnotic effect modulating neurosteroids formation increasing allopregnanolone (Allo) levels. Among the main enzymes involved in steroid synthesis, steroidogenic acute regulatory protein (StAR) and cytochrome P450 side-chain cleavage (CYP 450scc) have a major role in cholesterol turnover and neurosteroids formation in mitochondria (7). Among the neurosteroids that have involved in pain perception, are the 3a,5a reduced metabolites of progesterone, such as 3a-hydroxy-5a-pregnane-20-one or Allo. This latter neurosteroid, as well as tetrahydrodeoxycorticosterone, is known for its beneficial effect in attenuating pain behaviour (8).
Here, we have hypothesized that PEA, acting as ligand of endogenous PPAR-α, may play a role in CNS neurosteroid formation, as a mechanism underlying PEA effect. For this aim, using C6 glioma cell line and primary murine astrocytes, we have explored the capability of PEA to affect StAR activation and CYP450scc induction, leading to neurosteroid synthesis. Silencing of PPAR-a expression by using RNA interference or a pre-treatment with the PPAR-a antagonist GW6471 was performed to evaluate the involvement of this receptor in PEA induction of neurosteroid synthesis.
Low concentrations of PEA (1-3 mM) induced a weak proliferative effect, while 10 mM of PEA did not modify cell viability. At 30-300 mM, PEA led to a significant and concentration-dependent decrease of cell viability. Survival percentage observed after 24 h of incubation did not significantly change during time up to 4 days. Moreover, we showed that the stimulation of C6 cells with PEA led to an increase in StAR protein. An increase in CYP 450scc expression in the mithocondrial fraction was also observed. Both effects were completely blunted by the pre-incubation of cells with the PPAR-a antagonist, GW6471. Consistent with these findings down-regulation of PPAR-a in C6 cells by RNA interference led to failure of PEA in modulating StAR and CYP 450scc.
To confirm our hypothesis, we also measured the amount of allo released in the supernatant after 24h PEA stimulation. Allo was significantly increased and its synthesis was reverted at basal level by GW6471 pre-treatment. PEA effect was also confirmed on primary murine astrocytes, showing an increase of StAR and CYP 450scc in the mitochondrial fraction, that was blunted by GW6471 pre-incubation of astrocytes.
Further studies are needed to verify the physiological role and pharmacological properties of PEA in CNS, where PEA is found in significant levels in whole mouse or rats brains and could play homeostatic and protective role both in physiological and pathological conditions, when its concentration increases (5).

USE OF PALMITOYLETHANOLAMIDE (PEA) FOR CONTROLLING PAIN IN SMALL ANIMAL VETERINARY MEDICINE: PRE-CLINICAL AND CLINICAL DATA

A Miolo, MF della Valle

The ever-increasing physical and emotional relationships between human beings and pets, together with the recent scientific breakthroughs, have currently given rise to a much greater attention to the assessment and management of pain in dogs and cats [1-5].
Feline and canine pain can originate from a variety of conditions, ranging from osteoarthritis (OA) to lower urinary tract diseases (LUTDs). Dermatologic disorders are also recognized as important source of acute and chronic pain. Moreover, pruritus, i.e. the clinical sign more frequently detected in small animal skin diseases, is known to share many similarities to pain. Unmyelinated nerve fibres for itch and pain both originate in the skin; nociceptors and pruriceptors are morphologically indistinguishable; itch and pain are conveyed centrally in two distinct systems that both use the same peripheral nerve bundle and spinothalamic tract [6].
Many biologically active substances able to sensitize nociceptors and pruriceptors have been discovered. Histamine, tryptase, chymase, and growth factors (e.g. TNF-alpha, NGF Nerve Growth Factor) are among these mediators and they are all synthesized and released upon activation by mast cells (MCs). MCs are in close connection with microvessels and sensory fibres [7] and MC products may contribute to pain sensation through the activation/sensitization of innervating primary afferent nociceptors either directly, or indirectly through sympathetic fibres [8]. A self-reinforcing loop between mast cells and sensory/sympathetic nerves may thus act to sustain both the neurogenic inflammatory component and the hyperalgesia typically associated with tissue injury/noxious perturbations. A great deal of evidence actually shows that activated MCs contribute importantly to neuropathic and inflammatory pain by releasing nociceptive, pruritogenic and inflammatory mediators after degranulation [8,9].
Palmitoylethanolamide (PEA) is the naturally occurring amide of palmitic acid and ethanolamine, and belongs to the superfamily of N-acylethanolamines. PEA attracted attention for the first time in 1957, when it was discovered that the compound isolated from soybeans, peanuts, and egg yolk has anti-inflammatory activity [10]. In 1965 it was shown that N-acylethanolamines also existed in mammalian tissues [11]. It was in the mid 1990s that PEA received renewed attention, when the research group headed by the Nobel Prize Winner Rita Levi Montalcini coined the acronym ALIA (Autacoid Local Injury Antagonism) to describe that the local production of PEA and congeners may lead to inhibition of both inflammation and the sensitising effects of inflammatory products on nociceptive processes. It has originally been proposed that the ALIA mechanism acts trough down-regulating mast cell activation and deleterious cellular processes following pathological events [12,13]. Since then, other hypotheses have been put forth to explain the mechanism of how PEA and other aliamides actually work (e.g. the entourage hypothesis and the activation of particular receptors, as the intracellular receptor PPAR-alpha) [14]. More recently, it has been shown that the endocannabinoid-like compound PEA is produced on demand and accumulates locally during several inflammatory and painful disorders, i.e. intestinal inflammation [15], chronic migraine [16], neuropathic pain [17,18], focal cerebral ischemia [19] and multiple sclerosis [20]. PEA levels also increase in response to UV-B irradiation in mouse epidermal cells [21] and in dermatitis skin lesions [22]. Interestingly, in the lesional skin of atopic dogs PEA levels are 30 times higher than in normal canine skin [23]. The increase in PEA levels is universally considered to play important protective roles [24]. PEA indeed exerts anti-inflammatory and anti-hyperalgesic effects in various animal models of inflammation and pain [24,25] (Table) and it has been suggested to function as an endogenous regulator of nociception [26]. Notably, a symposium has recently been dedicated to PEA within the Congress of the Italian Pharmacological Society (*).

TABLE – The main anti-inflammatory and anti-hyperalgesic effects of PEA

	Model	Dose	Main effect	Ref.
Inflammation (in vitro)	LPS-stimulated hPBM cells	30-300 nM	Inhibition of IL-4, IL-6 and, IL-8 production; decreased release of p75 TNF-α soluble receptor	[27]
	Antigen-stimulated RBL-2H3 cells and RPMCs	EC_{50} 0.3μM	Profound reduction of antigen-evoked serotonin release	[28]
	LPS-stimulated macrophage cell line RAW264.7	10μM	Significant inhibition of NO production	[29]
	LPS-stimulated adipocytes	100 μmol/l	Significant inhibition of TNF-α secretion	[30]
	Immunologically-challenged canine skin mast cells	10^{-5} – 10^{-6} M	Inhibition of histamine, PGD2, and TNF-α release	[31]
	Cultured keratinocytes challenged with poly-(I:C)	0.1, 1, 10 μM	Strong reduction of the chemokyne MCP-2	[22]
Acute inflammation (in vivo)	Neurogenic inflammation (SP in the ear pinna of rats)	0.1, 1, 5, 20 mg/kg s.c.	Significant inhibition of skin mast cell degranulation	[12]
	Neurogenic inflammation (SP in the ear pinna of rats)	0.1, 1, 10 mg/kg p.o.	Significant and dose-dependent inhibition of skin mast cell degranulation and plasma extravasation	[32]
	Carrageenan-induced rat paw oedema	3 - 10 mg/kg p.o.	Reduction of carrageenan-induced oedema n a time- and dose- dependent manner	[32]
	Passive cutaneous anaphylaxis in mice	1 mg/kg p.o.	Significant inhibition of PCA-induced extravasation	[32]
	Formalin-induced rat hind paw oedema	10 mg/kg p.o.	Significant reduction of paw oedema	[32]
	Dextran-induced oedema in the rat	0.3, 1, 3 mg/kg p.o.	Significant and dose-dependent reduction of hind paw oedema formation	[32]
	Carrageenan-induced rat paw oedema	10 mg/kg p.o.	Inhibition of paw oedema	[33]
	Carrageenan-induced rat paw oedema	1, 3, 5, 10 mg/kg p.o.	Inhibition of paw oedema when PEA is given after inflammation is established (curative efficacy), and inhibition of NO production	[34]
	TPA-induced ear oedema in mice	Topical, 15 and 150 nmol/cm^2	Significant reduction of oedema	[35]
	Carrageenan-induced paw	10 mg/kg i.p.	Significant decrease of oedema	[35]

		oedema in mice		
		Carrageenan-induced paw oedema in mice	0.01-1μg i.c.v.	Significant decrease of oedema, and of COX-2 and iNOS expression [36]
		LPS-injected mice	3, 30, 200 mg/kg i.p.	Very strong anti-inflammatory effect (reduced levels of circulating TNF-α) [30]
		Allergic dermatitis in Beagle dogs	3, 10, 30 mg/kg p.o.	Significant reduction of the wheal area induced by both antigen and anti-canine IgE challenge [37]
		DNFB-induced contact dermatitis in mice	5-10 mg/kg i.p.	Significant reduction of inflammation (ear thickness) [22]
		TMEV-IDD model of multiple sclerosis in mice	5 mg/kg i.p.	Improvement in the motor function [20]
Inflammation		s.c. implant of λ-carrageenin-instilled sponge in mice	50 μg/sponge	Significant reduction of leukocyte infiltration [38]
	Chronic (in vivo)	s.c. implant of λ-carrageenin-instilled sponge in rats	200, 400, 800 μg/ml	Significant and concentration-dependent decrease in granuloma formation and local angiogenesis [39]
		Carrageenan-induced hyperalgesia in rats	10 mg/kg p.o.	Significant reduction of mechanical hyperalgesia [32]
		Formalin-evoked nociception in mice	5, 10 mg/kg i.a.	Significant reduction of the second phase behavioural response [40]
		Carrageenan-induced hyperalgesia in rats	10 mg/kg, p.o.	Abolishment of hyperalgesic response [33]
		Formalin-evoked nociception in mice	5, 50 μg/animal (i.pl. injection)	Marked inhibition of pain behaviour [41]
		i.pl. NGF - induced hyperalgesia in rats	10, 25 mg/kg i.p.	Significant reduction of hyperalgesia and neutrophil accumulation [42]
		tail flick test in mice	5, 10, 50, 100 mg/kg p.o.	Remarkable decrease in antinociception behaviours [43]
		Formalin-evoked nociception in mice	5, 10, 50, 100 mg/kg p.o.	Significant antinociceptive activity in both early and late phase [43]
Inflammatory pain		i.pl. carrageenan-induced hyperalgesia in mice	0.01, 0.1, and 1 μg i.c.v.	Marked reduction of mechanical hyperalgesia in a time-dependent manner [44]
	somatic	Hyperalgesia evoked by s.c. implant of λ-	800 μg/ml	Significant reduction of new nerve formation and strongly reduction of granuloma- [45]

	carrageenin-instilled sponge in the rat		associated hyperalgesia	
	Turpentine inflammation of the rat urinary bladder	10, 20, 30 mg/kg i.a.	Significant attenuation of the vesical hyper-reflexic response	[40]
	Acetic acid-evoked writhing in mice	1, 20 mg/kg i.p.	Dose-dependent attenuation of the writhing response	[41]
	Turpentine inflammation of the rat urinary bladder	10, 25 mg/kg i.p.	Attenuation of referred hyperalgesia in a dose-dependent fashion	[46]
	Kaolin-evoked writhing in mice	0.1 - 10 mg/kg i.p.	Potent inhibition of the nociceptive response	[41]
	Magnesium sulphate-evoked writhing in mice	1-10 mg/kg i.p.	Dose-dependent inhibition of the nocifensive response	[41]
	NGF-induced inflammation of the rat urinary bladder	2.5 mg/kg i.a.	Significant increase of micturition threshold and significant reduction of spinal cord Fos production	[47]
visceral	Acetic acid-evoked writhing in mice	50, 100 mg/kg p.o.	Significant reduction of the number of writhes	[43]
	Spinal cord injury in mice	10 mg/kg i.p. before or after surgery	Significant reduction of the severity of spinal cord trauma and of the spinal cord levels of TNF-α, IL-1β, iNOS	[48]
Neuropathic pain	Chronic constriction injury of sciatic nerve in mice	10 mg/kg i.p. once daily for one week	Significant relief of thermal hyperalgesia and mechanical allodynia	[49]

Abbreviations used in the table - DNFB, 2,4-dinitrofluorobenzene; i.pl., intraplantar; LPS, bacterial lipopolysaccharide; poly-(I:C), polyinosinic acid-polycytidylic acid; RBL-2H3, rat basophilic leukemia cells of the secreting subline 2H3; RPMCs, rat peritoneal mast cells; TPA, phorbol ester 12-O-tetradecanoylphorbol-13-acetate; TMEV-IDD, Theiler's murine encephalomyelitis virus-induced demyelinating disease.

The anti-inflammatory and anti-hyperalgesic effects of PEA summarized in the Table are partly mediated by mast cell down-modulation [47,50]. Particularly, ultramicronized PEA, whose veterinary use is patented by Innovet Italia, down-modulates mast cell degranulation both in vitro and in vivo [31]. A clinical study on cats with eosinophilic granuloma and eosinophilic plaque revealed that PEA (10 mg/kg/30 days/p.o.) not only down-regulates skin mast cell degranulation, but also reduces cutaneous signs and lesions [51]. A randomized, double blind, placebo controlled study confirmed the ability of PEA (15 mg/kg/45 days/p.o.) to reduce inflammatory-related signs in atopic dogs [52].

PEA is currently used to control inflammation and pain in some small animal veterinary products indicated for skin diseases and LUTDs [14], under the trademark of Redonyl® and Urys® respectively.

A PEA congener, namely N-palmitoyl-D-glucosamine or Glupamid®, is included in a chondroprotective nutraceutical for canine and feline OA, and has been shown to down-modulate mast cell mediator release [53]. A preliminary ongoing study has recently shown that a 7-day Glupamid® treatment (10 mg/kg, p.o., sid) significantly attenuated mechanical allodynia in a time-

dependent manner in a murine model of osteoarthritis pain (Costa B., personal communication).
The evidence collected so far provide a strong rational basis for the use of PEA as the management modality of choice for canine and feline pain, of both inflammatory and neuropathic origin.

The transient receptor potential (TRP) superfamily of non-selective cation channels includes 6 subfamilies: TRPC ('Canonical'), TRPV ('Vanilloid'), TRPM ('Melastatin'), TRPP ('Polycystin'), TRPML ('Mucolipin'), and TRPA ('Ankyrin') channels. TRP channels are six transmembrane (TM) domain integral membrane proteins, with cytosolic C- and N-terminal domains, and a non-selective cation-permeable pore region between TM5 and TM6. The various subfamilies differ particularly for the number of ankirin repeats present in their N-terminus, which is null in TRPM and very high in TRPA channels. Over 50 members of the TRP family have been characterized in yeast, worms, insects, fish, and so far 28 in mammals. They are involved in the trasduction of a remarkable range of stimuli including temperature, mechanical and osmotic stimuli, electrical charge, light, olfactive and taste stimuli, hypotonic cell swelling, xenobiotic substances and endogenous lipids. Importantly, mutations in different TRPs have been linked to human diseases, and their expression in tissues affected by pathological conditions is often increased (1).
TRP channels of the vanilloid-type 1-4 (TRPV1-4), ankyrin type-1 (TRPA1) or melastatin type-8 (TRPM8) are deeply involved in thermosensation, pain transduction and inflammation. They are expressed in sensory fibers of A□ and C-type, in dorsal root (DRG) and trigeminal ganglia as well as in perivascular neurons, with TRPV1 (the "capsaicin receptor") and TRPA1 (the "mustard receptor") being often co-expressed in the same neurons. Whilst TRPV1-4 are activated by high temperatures, TRPA1 and TRPM8 (the "menthol receptor") are activated by cold. TRPV1 is also activated by low pH, such as during certain inflammatory conditions, as well as by several pro-inflammatory mediators, and this leads to release of algogenic peptides (substance P, CGRP) from sensory neurons, thus contributing to neurogenic inflammation. TRPA1, instead, is activated by numerous irritants. TRPV1 is also expressed in central neurons, and, at the supra-spinal level, is abundant in neurons of the periaqueductal grey (PAG) and rostral ventrolateral medulla (RVM), where it modulates the descending pathway of antinociception. Contrary to its role in the spinal cord and sensory afferents, TRPV1 in the PAG-RVM contributes to descending antinociception, and it does so by enhancing both glutamatergic signalling/OFF neuron activity in the RVM and □-opioid receptor-mediated analgesia (2,3).
In DRG neurons as well as in spinal cord and in the PAG and RVM, TRPV1 is also co-expressed with cannabinoid CB_1 receptors, with which this channel shares some endogenous agonists, i.e. anandamide and *N*-arachidonoyl-dopamine, known as endovanilloids/endocannabinoids. TRPV1 and CB_1 can either act in concert or oppose each other at modulating pain through sensory or supra-spinal pathways, and this cross-talk might occur through several mechanisms (4). Furthermore, some non-psychotropic cannabinoids from *Cannabis sativa* with little or no activity at CB_1 receptors, such as cannabidiol (CBD) or cannabichromene (CBC), activate instead TRPV1, TRPV2 and/or TRPA1 channels, or potently antagonize TRPM8 channels (5). Importantly, CBD can both activate and desensitise TRPV1, TRPV2 and TRPA1 channels, and this property endows the compound with the capability of potentially influencing nociception and inflammation in several ways, also at the supraspinal level (5-7). These interactions will be described and new data on the effects of CBD and CBC on the descending pathway of antinociception, obtained by my group together with Prof. Maione's group, will be presented at the conference.

Introduction

Oxytocin (OXT) is a nonapeptide synthesized in the paraventricular (PVN) and the supraoptical (SON) nuclei in the hypothalamus, its receptors are widely distribute in the CNS, including cortex, olfactory system, basal gangalia, limbic system, thalamus, hypothalamus, brain stem, and dorsal horn of the spinal cord [1]. OXT performs its biological functions through OXT receptor functionally coupled to Gq/11α class GTP binding proteins that stimulate together with G β/γ, the activity of phospholipase C-β isoforms [1]. Several studies have reported that OXT modulates analgesia or nociception [2; 3], and that the endogenous opioid system may be involved [4]. Moreover, a series of physiological and pharmacological studies have shown that OXT acts on autoreceptors to elevate intracellular Ca^{2+} [5; 6]. Although many authors have reported and are in agreement on analgesic action of OXT, the mechanism has not been well elucidated. Some studies suggest in fact, that OXT has no effect on nociception [7] and attribute the OXT increased latency responses on the hot plate test to the sedative and vasoconstrictive effects of this peptide [8]. On the other hand, several manuscripts suggest that OXT-induce analgesia or nociception could be due to the interaction with opioid system [9; 4]. Indeed, Miranda-Cardenas and co-worker [10] have show that the endogenous released OXT induced by electrical stimulation of the paraventricular nucleus of hypothalamus or direct application of OXT on the spinal cord produced a clear analgesic effect, which was reduced significantly when naloxone was intrathecally injected before the stimulation of the paraventricular nucleus and OXT administration [10]. Recently, an interesting hypothesis suggest that OXT releases from presynaptic cell may activate local Ca^{2+} stores [5; 6] producing a second molecule such as endocannabinoid [11; 12; 13], which in turn then function as retrograde transmitter [14].

Aim

The aim of present study was to investigate a possible role for OXT receptors at the CNS level in mediating peripheral pain. In particular, we examined the antinociceptive and the anti-inflammatory effects of OXT and, in particular, we studied the role of the opioid and cannabinoid systems in OXT-induced antinociception in carrageenan-induced paw oedema.

Animals. and Chemicals.

Male Swiss mice weighing 30-33 g were purchased from Harlan (Udine, Italy). OXT**,** naloxone**,** nor-binaltorphimine ***(nor-BNI), naltrindole***, were purchased from Tocris Cookson Inc. (Bristol, UK). All other chemicals were from Sigma-Aldrich (Milan, Italy).

Intracerebroventricular Injections.

Animals were briefly anesthetized with enflurane. Drugs were administered in a volume of 2 μl per mouse by using a 25-μl glass Hamilton syringe Hamilton Co. (Reno, NV) with a stainless steel needle modified with a shaft to control the depth of injection at 2 mm. The injection was made into the lateral ventricle 2 mm caudal and 2 mm lateral from the bregma.

Paw Oedema

Paw oedema was induced by a sub-plantar injection of 50 μl of sterile saline containing 1% λ-carrageenan into the left hind paw. Paw volumes were measured by a plethysmometer (Ugo Basile, Milan, Italy) at different time intervals.

Mechanical hyperalgesia

Mechanical hyperalgesia was assessed by measuring of latency (s) to withdraw the paw away from a constant mechanical pressure exerted onto its dorsal surface.

Statistical Analyses.
Results are expressed as the mean ± S.E.M. of n experiments. All analyses were conducted using Graph-Pad Prism (GraphPad Software Inc., San Diego, CA). The significance of differences between groups was determined by two-way analyses of variance (ANOVA) followed by Bonferroni post hoc tests.

Results and Discussion

Many studies have been demonstrated that OXT is involved in pain modulation in the central nervous system [7; 10]. Central treatment (icv) with OXT has an analgesic effect in a patient with intractable cancer pain [15], moreover, OXT in the spinal cord relates to antinociception in the dog [16]. Moreover, Yang and co-worker [19], proved that OXT takes part in the chronic and acute low back pain in the human. Our studies showed that OXT increased paw withdrawal latency only following central administration (30ng/mouse-icv), while peripheral injection (1mg/kg-i.p. and 50μg/paw-i.pl.) did not produce any effect on carrageenan-induced hyperalgesia. For confirmed involvement of central OXT receptors, we used atosiban, a specific antagonist OXT receptors. Central co-injection of OXT (30 ng/mouse) and atosiban (1μg/mouse), has produced a reduction OXT-induce antihyperalgesic effect. Previous studies had proven that OXT induces the spinal cord releasing endogenous opiate peptides, and that the OXT analgesic effect can be reversed by opiate receptor antagonist [9; 17; 10]. The mechanism of OXT regulating analgesia may be proposed as follows: OXT is released from PVN and/or SON during pain stimulation, and then transported to the other brain nuclei and spinal cord, where OXT influences the other antinociceptive system such as endogenous opiate peptide system to take part in pain modulation. Previous studies showed that OXT-induced antinociception could be blocked by the non-selective opioid receptor antagonist naloxone in the supraspinal level [18]. In the present study OXT-induced antinociceptive effect to mechanical stimulation was attenuated by i.c.v. injection of the selective opioid receptor antagonists beta-Funaltrexamine (β-FNA 1ug/mouse; μ-antagonist) and nor-binaltorphimine (nor-BNI 10 nmol/mouse; k-antagonist), but not by naltrindole (10 nmol; δ-antagonist), indicating that mu and kappa opioid receptors, not delta opioid receptor, are involved in the OXT-induced anti-nociception in the brain. These findings are supported by sereral papers [19; 9, 4]. Moreover, a series of physiological and pharmacological studies have shown that OXT acts on OXT auto-receptors to elevate intracellular Ca^{2+} [5; 6]. On basis of this, we have supposed that dendritically released OXT act on presynaptic OXT cell activated Ca^{2+} stores this event is well know to lead to endocannabinoid (eCB) release [11; 12; 13]. Consequently, we explored whether activation of OXT receptor was a prerequisite to the production and subsequent actions of eCB. Our results showed that CB1 antagonist, SR141617A (1 μg/mouse), reduced antihyperalgesic effect of OXT, whereas, a specific CB2 antagonist, SR144528 (1 μg/mouse), did not modify OXT activity, suggest a key role only for the CB1 receptor. Recent reports have highlighted the interaction of the endogenous cannabinoid (CB) system with central hormone release in the modulation of magnocellular neuron synaptic physiology [12; 20]. It is conceivable that OXT may diffuse further eCB, and thus, allow eCB action on many cells to co-ordinate activity, transforming a local effect to a global one.

The present study clarifies that OXT plays a key role in modulation of pain pathway. In particular, following activates of OXT central receptors, the nonapeptide is able to reduce carrageenan-induce hyperalgesia but it do not modify oedema development. Moreover, our results indicate that μ- k-receptors, and CB1-receptor, are involved in the OXT-induce antihyperalgesic effect in the central nervous system.

CENTRAL PPAR-ALPHA ACTIVATION REDUCES PAIN AND HYPERALGIA IN MICE VIA NUCLEAR FACTOR KB INHIBITION

Giuseppe D'Agostino, Giovanna La Rana, Roberto Russo, Oscar Sasso, Carmen Avagliano, Anna Iacono, Rosaria Meli, Antonio Calignano.
Department of Experimental Pharmacology, University of Naples Federico II, Naples, Italy.

Peroxisome proliferator-activated receptor alpha (PPAR-alpha) is a ligandactivated transcription factor belonging to the nuclear hormone receptors and suggested to be involved in inflammation and pain control. Little is known about its role at CNS level. We report that spinal and dorsal root ganglia PPAR-alpha expression is modulated by a peripheral inflammatory or a painful stimulus, and central administration of endogenous or synthetic PPAR-alpha agonists reduces both pain perception and inflammatory hyperalgesia in mice. Under inflammatory pain state, central PPAR-alpha activation modulates NF-kB nuclear signalling along sciatic nerve, dorsal root ganglia and spinal cord. Moreover, we evidence that PPAR-alpha receptor may physically reduce NF-kB activation during the early phase of pain signalling. In vivo co-immunoprecipitation experiments reveal a physical interaction between PPAR-alpha and NF-kB complex subunits. This interaction was strongly and rapidly increased in lumbar spinal cord of mice subjected to the formalin nociception test. To understand if the enhanced interaction would function as a reducer of pain-evoked intracellular machinery, we used an in vitro approach. In SH-SY5Y neuroblastoma cells substance P stimulation induced the PPAR-alpha/NF-kB interaction in few minutes, similarly to that observed in vivo. GW7647, a synthetic PPARalpha agonist and pain-reducing compound, increases this complex formation. We conclude that i) PPAR-alpha-mediated reduction of persistent pain may likely rely on reduction of the NF-kB activity and inflammatory central sensitizer synthesis, ii) while the contribution to acute pain responses may be in part related to constitutive activity of both these transcription factors in neurons of the nociceptive system

NEUROPATHIC PAIN: LOOKING FOR A DISEASE MODIFYING AGENT

L. Di Cesare Mannelli, C. Ghelardini

University of Florence, Department of Preclinical and Clinical Pharmacology, Viale Pieraccini 6, 50139, Florence, Italy
lorenzo.mannelli@unifi.it

Neuropathic pain is an unpleasant, abnormal signalling associated with injury or malfunction in the peripheral or central nervous system (CNS). These widespread disorders are induced by metabolic insult or trauma, autoimmune diseases, infections, drug or toxin exposure, and by cancer or viral chemotherapy. Neuropathies are extremely difficult to treat and actual therapies are generally palliative and include conservative non-pharmacological therapies, drugs and more invasive interventions. Available drugs for pain improvement are not able to revert the nervous alteration or to induce tissue regeneration [1]. On the other hand, many growth factors for the nervous system do not relieve pain. NGF, the prototypical neurotrophic factor, maintains the survival of sympathetic and sensory neurons as well as neurite outgrowth but it also exerts profound biological effect on nociceptors that express high-affinity NGF receptors [2]. Therefore, a great deal of interest has evolved around the research of compounds able to decrease hyperalgesia and to induce, at the same time, neuroprotection or neuroregeneration.
Pain is the common symptom due to variable nervous tissue alterations leading to different neuropathies. Traumas induce morphological changes evident also further than the lesion site. Damage to peripheral nerve are able to induce a decrease in myelin thickness, axon diameter and number of fibers in the proximal and, at a lesser extent, in the distal part of the nerve. An important inflammatory component is present as oedema and macrophagic infiltrate [3]. Moreover, in a model of peripheral neuropathy induced in the rat by loose ligation of the sciatic nerve (Chronic Constriction Injury; CCI) the activation of the apoptosis cascade has been described both in proximal and distal portion of the nerve. A mitochondrial damage alters membrane permeability, cytochrome C is released in the cytosol and triggers the signal up to the fragmentation of the genome [4]. Animal treatment with Acetyl-L-Carnitine (ALCAR; 100 $mgkg^{-1}$ i.p. twice daily for 14 days), but not with L-Carnitine or Gabapentin, prevents apoptosis induction. ALCAR is also able to prevent hyperalgesia and both the anti-apoptotic and the anti-hyperalgesic effects are reverted by the nicotinic receptor (nAChR) antagonist mecamylamine [5]. On the other hand, in the same model, acute administration of the alpha7 nAChR agonist PNU-282987, 10 and 30 mg kg^{-1} p.o. (15 days after ligation), is able to reduce hyperalgesia in a methyllicaconitine-reversed manner. This alpha7 nAChR agonist exerts no analgesic effects. Chronic PNU-282987 treatments, 30 mg kg^{-1} once a day for 7 days and 10 mg kg^{-1} for 28 days are able to decrease pain perception. Repeated treatments with PNU-282987 reduce the presence of oedema and macrophagic infiltrate and, on the coronal sections of the nerve, a significant higher myelin sheath, axonal diameter and number of fibers are observable [3].
In other neuropathies, like those chemotherapy-dependent, the effect of neurotoxicity is lesser pronounced and detectable and a smir of light signs diffuse from the peripheral to the central nervous system has been highlighted. Characteristically, no inflammatory responses are present. Both neuropathy groups, with inflammatory or without inflammatory alterations, show as common characteristic a glial activation in CNS. Astrocytes and microglia have well-documented roles in pain [6]. Although astrocytes and microglia in the CNS each have unique roles in the modulation of neuronal function [7], they do have some overlapping actions. Both cells types are key mediators of the CNS innate immune response. Growing evidences ascribe to glia pathological effects as neuronal hyperexcitability and chronic inflammation. Spinal microglia have been recognized as pivotal in the initial phases of neuropathic pain, whereas astrocytes may be involved in the maintenance [8,9]. On the other hand glia has a number of housekeeping function, among them

neuroprotection [10,11]. It is important to consider that both astrocytes and microglia are necessary for the homeostasis of the environment surrounding neurons, and also for the regulated clearance of apoptotic cells.

A major challenge that new drug-development strategies for the treatment of neuropathic pain face is targeting the pathological and pain trigger actions of astrocytes and microglia without altering their protective and recuperative roles. In order to evaluate the glia role in neuropathic pain, we recently described a decrease of the anti-hyperalgesic growth factor Artemin a member of the glial cell line-derived neurotrophic factor (GDNF)-related family in the CCI model. The neuroprotective compound ALCAR is able to normalize this expression level as well as to induce Artemin expression in sham rats [12]. Topic of debate is whether this ALCAR effect is due to a nicotinic mechanism. nAChR signalling has a major role in the glia-neuron network, in particular alpha7 nAChR is expressed in microglial cells [13] and its activation attenuates the pro-inflammatory response of microglial cultures [14]. Also astrocytes express this receptor subtype but their possible functional role is poorly understood [15]. In conclusion, glia is strongly involved in neuropathic pain as well as in neuroregenerative mechanism and the stimulation of the glia-expressed alpha7 nAChR shows anti-hyperalgesic and neuroprotective effects. Further understanding of the molecular mechanisms that underlie the effects of glia on neuropathy processing and more evidences about the importance of nAChRs in the signal switch between pain and regeneration should lead to the development of new and more efficient approaches for the clinical management.

ENDOCRINE EFFECTS OF "NEW OPIOIDS" IN CHRONIC PAIN IN WOMEN OF DIFFERENT AGES

M.C. Pace, M. Iannotti, P. Sansone, V. Pota, M.B. Passavanti

Second University of Study of Naples, Department of Anesthesiologycal, Surgical and Emergency Sciences, Piazza Miraglia 2, 80100 Naples, Italy;

Introduction

Chronic non cancer pain affects one fourth of European population, the majority being women (1). The need to treat pain compels physicians to use opioids for long periods even though opioids can affect the hypothalamus-pituitary axis (2). Indeed both endogenous (β-endorphin) and exogenous opioids are known to modulate the secretion of pituitary hormones, including gonadotropins. In men, morphine administration was found to induce persistent, long-lasting hypogonadism. Indeed substantial evidences indicate that gonadal hormones can influence the structure and functions of neurons during development and also in adulthood, including alterations of their dendrites and synaptic connections. Hajszan describes some studies showing that synaptic connectivity in the hippocampus and prefrontal cortex of male rats, normally depends on androgens. When adult males are castrated, the number of synapses in each region decreases. It is also suggested that androgens might be an effective therapeutic for certain neurological disfuntions such as Alzheimer's disease and schizophrenia. The effects on androgens have been described in men, already the opioid-induced hypogonadism has also been shown also in women with clinically relevant features. It is necessary to find solutions able to support the use of opioids in pain therapy without deleterious side effects like hypogonadism. As regards the efficacy/side effects ratio, 'new' opioids such as buprenorphine are indicated as one of the best/first choices, also in view of the possibility to administer the drug via a patch. Buprenorphine (BP) is a centrally-acting analgesic that binds to μ-opioid receptors (MOR, partial agonist) and k-opioid receptors (antagonist) with high affinity. Many studies have described the good analgesic effects of this drug, its high safety and the good compliance by patients (3). Moreover Ceccarelli et al. described that buprenorphine does not affect testosterone levels in the brain of male rats (4). We conducted a trial to assess the efficacy and the effects of buprenorphine TDS for 6 months in women in reproductive age or in menopause. Furthermore, a number of hormonal determinations where carried out to study the effect of buprenorphine on HPG axis.

Methods

Subjects were recruited in the Second University of Naples, while hormonal determinations were carried out in the Pain and Stress Neurophysiology lab of the University of Siena. The protocol, in accordance with the ethical standards of the Declaration of Helsinki, was approved by the Institutional Ethic Committee. Patients signed an informed consent before participation.

Female outpatients of at least 18 years of age, suffering non-cancer, musculoskeletal pain (low back pain) with VAS > 6 were asked to participate in the study. The exclusion criteria were: neurological pathologies; cardiac, respiratory, metabolic, hepatic, renal, gastrointestinal, heavy and/or uncompensated pathologies; oncologic pathologies; HIV; endocrine alterations; psychiatric disorders; skin diseases; alcoholism and drug abuse; verified hypersensitivity to opioids; patients allergic to patches; pregnancy or lactation. This was an open prospective study for the evaluation of the analgesic efficacy and endocrine effects induced by long-term therapy with buprenorphine TDS 35 mcg/h to be changed every 72 h. After an interview including a pathological anamnesis and objective exam, each patient underwent an evaluation of pain through VAS, Mc Gill Pain Questionnaire Short Form (SF-MPQ) and PPI.

During the visit a blood sample was collected to determine blood and hormone parameters. Then a Buprenorphine TDS 35 mcg/h patch was applied.

The patients were instructed to use hydrochloride Buprenorphine sublingual tablets 0.2 mg, as rescue medication. As antiemetic prophylaxis they could take metaclopromide 10 mg.
Each patient was given a diary for the daily recording of VAS, adverse effects and use of rescue medication. After 15 days the patients made a control visit. The same procedure, the survey and controls and the blood sampling were replicated after 1, 3 and 6 months.

Statistical analysis

ANOVA with repeated measures was applied to all parameters. Multiple comparisons were carried with the Least Significant Difference (LSD) test when needed. The significance of the linear correlation coefficient (r) in the pre and post-M groups was tested using the Steel and Torrie procedure

Results

41 patients were screened to enrol 26 patients who met the inclusion criteria. 18 patients concluded the 6-month period, 8 patients discontinued the therapy for various reasons: adverse effects (constipation and somnolence, nausea and vomiting, n=4), patients decision (N=3) and medical decision (N=1).
The 18 patients admitted to the study were treated with Buprenorphine for 6 months. They were grouped into post-menopausal (10 patients, mean age 66.1 years, range 54-76), and pre-menopausal groups (8 patients, mean age 39.5, range 26-50).
The patients did not exhibit any significant collateral effects and none resorted to metoclopramide; the use of Buprenorphine tablets 0.2 mg as rescue medication was unnecessary and no buprenorphine TDS adjustments were required.
All patients recorded an improvement in their pain, as showed VAS, SF-MPQ and PPI; this result was present from the first month of treatment and persisted for the whole study (Table 1). Indeed ANOVA revealed a significant effect of time for the three parameters, in both age groups, due to the progressive decrease of their scores from basaline (T0) to the end.
Table 1: Pain parameters.

	Pre-M T0	T1	T3	T6	Post-M T0	T1	T3	T6
VAS	83.8	50.6 #	42.5 #	35.6 #	81	50.0 #	41.5 #	36.5 #
SF-MPQ	25.9	20.0 #	18.6 #	14.1 #	24.7	18.7 #	17.1 #	13.0 #
PPI	4.50	3.25 #	2.50 #	2.13 #	4.10	2.70 #	2.20 #	1.80 #

Vas: visual analog scale; SF-MPQ: short form-McQuill Questionnaire; PPI: present pain intensity
# $p<0.05$ vs T0 same group.
There were no statistically significant differences between the two groups in blood sugar, creatinine, protein or red and white cells. As regards azotemia, GOT, GPT, g-GT and haematocrit, ANOVA applied to the two groups determined at the 4 time points revealed significant differences (Table 2).
Table 2: Blood parameters.

Blood Parameters	**Pre-M T0**	**T1**	**T3**	**T6**	**Post-M T0**	**T1**	**T3**	**T6**

Luteinizing (LH) an Follicle-stimulating (FSH) hormones were higher in the post-M than pre-M women (p<0,01 and p<0,03 respectively) (Table 3).

In contrast to findings obtained with other opioids, in wich testosterone was drastically decreased, neither total testosterone (TT) nor free testosterone (fT), changed significantly for buprenorphine TDS treatment in either group of women (table 3). TT and fT levels were slightly higher in post-menopausal women at all determinations. Estradiol (E2) levels showed strong variation in the younger women still in the reproductive periods due to the difficulty in collecting blood on exactly the same day of the menstrual cycle (table 3).

Table 3: Hormones.

Hormones	Pre-M T0	T1	T3	T6	Post-M T0	T1	T3	T6
Total T ng/ml	0.12	0.16	0.20	0.20	0.20	0.20	0.21	0.21

# p<0.05 vs T0 same group; * p<0.05 vs Pre-M group, same period.

° (n=4 x group), in these hormones no statistics was carried out

Despite of this, as expected, E2 values were higher in younger women than in older ones.

Like testosterone, the cortisol (C) levels were not decreased by buprenorphine treatment. Indeed ANOVA revealed a progressive increase from baseline to the end. In post-menopausal women the increase was not significant, while in pre-menopausal women it was significant after 1 month of treatment (p<0.05).The multivariate analysis applied to the three main hormones TT, E2 and C, showed a significant effect over time point (p<0.01) only in the pre-menopausal group (p<0.01).

The correlation between VAS and hormones was significant in the pre-M group (R=0.34, p<0.001), in the not significant in the Post-M one (R=0.034, p>0.05).

Discussion

The important result of this study is that women treated for 6 months with buprenorphine TDS did not show the strong endocrine impairment observed with other opioids (5). Chronic, non cancer pain is a very big problem in our society. It affects, about 20% of the adult population and it is severe in 13% of cases. Moreover chronic pain mainly affects women, but few pharmacological experimentation has been done on them because of neurohormonal interferences. For this reason we investigate the effects of opioids on gonadal hormones, evaluating the results of the analgesic efficacy of the therapy in both reproductive-age and menopausal patients. The high analgesic power of these drugs makes them particularly efficient in the treatment of severe pain, but the risk of side effects and of addiction and tolerance phenomena, often affects their clinical use in prolonged treatments (6). OPIAD, i.e. opioid-induced androgen deficiency, mainly occurs in men treated with opioids, but it has also been found in women. Fatigue, anemia, absence of libido, bad mood and depression, are reported by patients treated with opioids. Buprenorphine, has repeatedly been shown to have some features different from the other commonly used opioids. Indeed in experimental animals and in patients it was found to cause a low level of addiction and it does not show a “roof

effect" if taken at therapeutic doses. Moreover recent studies have demonstrated that buprenorphine, unlike other opioids, exerts an antihyperalgesic effect, probably due to its antagonistic properties on k-opioid receptors (7). For these reasons we decided to use buprenorphine and we chosen the transdermal system because patients and doctors are amenable that: it is not invasive, lasts 72 hours and allows a constant release of the proximate principle with high therapeutic efficacy and low side effects. These characteristics can also be seen in the results of our study, which show in women, since the first patch application, a significant reduction in the pain symptomatology that persisted during the treatment, without significant variations in relation to the menstrual cycle and menopause. This early and constant positive trend made recourse to "rescue medication" unnecessary. VAS and the other pain parameters clearly decreased already after one month of treatment to remain low till the end of treatment.The results of the study are also encouraging in regard to side effects, particularly the nausea and vomiting that often follow opioid administration. In fact, in agreement with international literature, that reports a reduction of side effects with the use of buprenorphine TDS, none of our patients reported any significant side effects that needed treatment. This result underlines the key role of the administration technique in the genesis and the degree of side effects from opioids. We must, of course, consider the different responses to the therapy, often related to the patient's conditions, which also explains why 4 patients were excluded from the study after a short time. In fact, we believe it is very important to modulate the therapy according to individual needs. The blood parameters have never showed significant alterations that would justified the interruption of treatment. This is an interesting result since it reflects the absence of detrimental effects of buprenorphine TDS on body homeostasis. In previous studies on humans or experimental animals, gonadal hormones were found to be strongly affected by opioid intake. These effects were present in both sexes, although with some differences (8). In the present study, the considered steroid hormones (testosterone, DHT, cortisol) did not show any sign of decrease, infact, they tended to increase. In this study, testosterone was inversely related to VAS but only in pre-menopausal women. This was also true when all three hormones (testosterone, cortisol, estradiol) were considered all together. It is not easy to explain why the correlation was found only in the younger subjects because all recorded changes were apparently present in both groups, not only in the pre-menopausal one. However this strong correlation suggests that the presence of the menstrual cycle was significant. Indeed it was recently found in experimental females, that in addition to the hormone replacement, the cycle play a strong role in worsening the behavioral response to painful stimulation (9).

Functional changes in chronic pain

Neuropathic pain is a devastating and difficult to manage consequence of peripheral nerve injury, the main aspect of which is enhanced transmission of nociceptive messages [1]. In this condition, noxious stimuli are perceived as more painful (hyperalgesia), and normal, harmless stimuli may elicit pain (allodynia). Neuropathic pain may be considered a progressive nervous system disease that results from poorly-defined neurophysiological and neurochemical changes. Support for this hypothesis is obtained from animal models of chronic pain, in which a long-lasting increase in the excitability of pain-integrating neurons is observed. More recently, multidisciplinary research approaches have shown that chronic pain may be a consequence of long-term plastic changes along the entire pain matrix [2]. Apart from peripheral nociceptors and the spinal cord, morphological and functional plastic changes can also take place in cortical areas participating in pain processing. Indeed, growing evidence suggests that long term plastic modifications in cortical networks may represent a possible basic mechanism underlying chronic pain. Among cortical regions, anterior cingulate cortex (ACC), insular cortex (IC), primary (S1) and secondary (S2) somatosensory cortex, and prefrontal cortex (PFC) consistently respond to acute "physiological" pain stimuli in healthy subjects. However, if on the one hand the majority of the progress in cortex imaging studies of pain has been obtained in healthy subjects, much less is known about changes in cortical network functioning or responsiveness during chronic pain, and whether or not areas associated with physiological pain are also involved in chronic pain conditions. Intriguingly, PET or fMRI procedures have shown that spontaneous neuropathic pain seems to be more consistently associated with changes in thalamic activity and the medial (emotional) pain system. Thus, different "sources" of allodynia may induce distinct patterns of brain activity, reflecting different pathophysiological mechanisms and suggesting that specific "allodynia networks" in the cortex may exist [3].

Morphological changes in neuropathic pain

Apart from functional changes associated with chronic pain states, morphological alterations at spinal and sovraspinal level have been reported. Neuropathic pain has been shown to be accompanied by apoptosis of spinal cord cells [4], sprouting of nerve terminals in somatosensory cortex [5], grey matter density decrease in the prefrontal cortex, associated with reduced cognitive abilities [6]. In particular, Apkarian et al., showed by morphometric analysis that chronic back pain is associated with 5-10% of brain grey matter atrophy in prefrontal cortex and thalamus [6]. It is still not known whether the reduced grey matter density is related to projecting neurons, inhitory interneurons, microglia or all of these, and if it is the case, in which proportions. It has been demonstrated that mainly GABAergic interneuron population undergoes functional impairment at spinal level [7]. Further studies have reported that microglia is hyperactivated at spinal level after nerve injury [8] or proved inhibited in the cortex in chronic back pain [6].

Most of the data correlating cortical damage and chronic pain currently available come from human brain imaging, where it is difficult to identify the source of neuronal activity, namely excitatory vs inhibitory neurons. On this subject, the use of animal models remains the key approach to studying the basic mechanisms of chronic pain.

Changes in cortical caspases and cytokines

Changes in cortical caspase levels may represent an index of cell degenerative processes leading to cognitive deficit in chronic pain states. In particular, caspase-1 plays a pivotal role in controlling the

release of pro-inflammatory cytokines such as IL-1, which appears upregulated in the prefrontal cortex of rats with neuropathic pain [9]. Cytokines and chemokines contribute directly to the pathophysiology of neuropathic pain at peripheral, spinal and sovraspinal level [10, 11].

CB2 receptor agonists in neuropathic pain

It has been shown that cannabinoid receptor subtype 2 (CB2) attenuates the induction and maintenance of inflammatory and neuropathic pain [12, 13] by inhibiting the release of pro-inflammatory cytokines and chemokines. On this subject, this receptor may represent a new target to exploit in chronic pain therapy.

A preliminary study in our laboratory has shown that the gene expression of caspase-1, caspase-12 and caspase-8 (Fig.1) were significantly increased in the prefrontal cortex of neuropathic mice. Concomitantly, an increased staining of the IL-1ß, which correlates with astrocyte activation, and an increase in the active form of caspase-3 in microglia have been observed in the prefrontal cortex following spared nerve injury in mice (Fig.2). The occurrence of prefrontal cortex caspase-3 activation may imply microglial cell death and secondary neuronal functional impairment or damage following peripheral nerve injury and consequent neuropathic pain development.

The systemic administration of JWH-133, a selective CB2 receptor agonist, reduced mechanical allodynia and the mRNA levels of the pro-inflammatory caspase-1, caspase 8 and caspase-12.

Conclusion

These preliminary data open the way to considering changes in microglia/astrocyte activation as possible biomarkers of neural suffering during chronic pain states. On that subject, drugs such as CB2 agonists, which are able to change the activation of caspases and the release of particular cytokines, may represent a source for chronic pain modulation and to avoid consequent cortical impairment.

ANESTHETIC ACTIONS ON TONIC DESCENDING CONTROL OF THE SPINOTHALAMIC TRACT

Peter J. Soja

Faculty of Pharmaceutical Sciences, The University of British Columbia, Vancouver, BC Canada V6T 1Z3 Email: drpsoja@interchange.ubc.ca

Tonic descending inhibition (TDI) is an often reported but poorly understood property of lumbar sensory neurons. It is usually indicated in "acute" *in vivo* recording experiments when the excitability of a spinal sensory cell, *i.e.*, its spontaneous activity and/or responses to certain afferent inputs, is markedly enhanced during temporary removal of descending influences from the brain by the cooling of a spinal cord segment rostral to the recorded cell site. The reversibility of this release of descending tonic inhibitory control is revealed when the cooled spinal cord segment is subsequently re-warmed to restore axonal conduction in the spinal cord.

TDI is a common feature of lumbar dorsal horn neurons and certain sensory tract cells recorded in anesthetized, acutely prepared animal preparations that are subjected to extensive surgical procedures. However, it is not known whether the anesthesia and/or surgical preparation required for exposure of the spinal cord contribute to the development of TDI in acute experiments where TDI is commonly revealed. Consequently, further work on TDI in acutely anesthetized animal preparations, *vis-à-vis* TDI's mechanisms, pathways, and neurotransmitters, should be reserved until the existence and origin of TDI has been adequately documented in the conscious, intact animal and determined not to be an epiphenomenon of surgical trauma or general anesthesia. This represents an enormous undertaking and careful experimental design but a critical antecedant demonstration would be to confirm that TDI actually exists on classical spinothalamic tract (STT) neurons in conventional acute animal preparations. The following surveys the current state of knowledge regarding the phenomenon of TDI.

Electrophysiological Studies Almost one century ago, Sherrington and Sowton[1] and others [2-3] demonstrated that spinal cord transection results in augmented reflex movements suggesting that the brainstem exerted profound suppresser drives on spinal cord function. Engberg, Lundberg, and associates [4-5] later demonstrated that the medial medulla exerts an overall tonic suppressive action on spinal cord neuronal activities induced by flexor reflex afferents. In 1967, Wall utilized the technique of cooling a spinal cord segment rostral to the site of recording with frozen Ringer's solution to reversibly block axonal conduction within the spinal cord [6]. He found individual cells located in the lumbar dorsal horn laminae (I, IV, and VI) of the decerebrate cat preparation increased their spontaneous and peripherally-evoked discharge activities during a cold-block of the spinal cord over those observed in the normal state, which suggested the existence of TDI. Other spinal cells became more responsive to specific sensory modalities during a cold-block, *e.g.*, cells located in laminae IV and V became more responsive to C-mechanoreceptor and polymodal receptor input during spinal cold-block [6]. TDI appears in anesthetized acute preparations to be a consistent feature for lumbar interneurons or tract neurons comprising the spinocervical tract [7-8] and postsynaptic dorsal column (PSDC) pathway [9] which receive convergent A-□ and C fiber primary afferent input [6-8, 10-16]. Similar responses have been observed from "deep" unidentified neurons located in laminae IV-VI and deeper laminae (VII and VIII). These spinal gray regions contain neurons forming the spinothalamic tract (STT) [17-18], spinoreticular tract (SRT) [19-20], and dorsal spinocerebellar tract (DSCT) [21] but it should be noted that TDI has been assumed to impinge on STT neurons but has never been demonstrated for STT neurons in the rat, cat, or monkey.

Neural Mechanism(s) Underlying TDI The neural mechanisms underlying TDI of sensory tract neurons are not known but could arise as a result of direct active postsynaptic inhibition of ascending sensory tract neurons by relevant descending fibers or via inhibitory interneurons excited by descending facilitatory systems. Either of these two synaptic circuitries could account, in part,

for the commonly observed increases in spontaneous discharge activity of neurons recorded during cold-block of the spinal cord. Alternatively, disfacilitation, *e.g.*, a tonic presynaptic depolarization of primary afferent fibers [22] or postsynaptic inhibition of excitatory interneurons intercalated between primary afferent fibers and tract neurons, could produce TDI.

Origin of TDI Experiments performed in acute, barbiturate-anesthetized preparations suggest that TDI impinges on sensory neurons and emanates from the ventrolateral medullary reticular formation just ventral to the facial motor nucleus [13, 23] while TDI impinging on spinal neurons that convey reflex actions induced by the flexor reflex afferents in decerebrate, unanesthetized animals may originate in the medial reticular formation and may be even more "powerful" [4, 21, 24]. However, glycine and GABA applied by microiontophoresis into the ventrolateral reticular formation below the facial motor nucleus in the awake cat does not alter synaptic transmission through the SRT, SMT, and STT [25] suggesting that barbiturate anesthetics may shift the origin of the TDI generator(s) and/or specific brainstem centers may selectively mediate TDI of specific sensory channels. However, a comparative single unit recording study of TDI on separate STT neurons has not yet been performed.

Function of TDI The function of TDI remains cryptic but could be involved in the gain of motor reflexes [5], autonomic somatoreflex integration [26-27], or inhibition of the development of spinal interneuron plasticity [28-30]. TDI could also arise from activity in small (un)myelinated primary afferents [20, 31] suggesting that TDI could be an epiphenomenon of surgical procedures involved in spinal cord exposure prior to unit recording studies [32-38]. Integration of the findings from these acute studies with the results of chronic studies suggest that TDI could be operating omnipresently on second order tract neurons to filter sensory information, waxing and waning in a manner appropriate to the animal's behavioral repertoire. For example, TDI has been suggested to operate during arousal associated with feeding, [39] attention, [40-41] locomotion, [42] or during wakefulness and the transition to sleep. During wakefulness, TDI may dampen sensory inflow via diencephalospinal DA pathways while during REM sleep, TDI could act in concert with other inhibitory drives, *e.g.*, glycine, impinging on motoneurons [43] to suppress sensory inflow via ascending sensory pathways. [43-49] However, no direct data quantifying TDI under control and test conditions truly exists to date to support any of these functional possibilities.

Neuropharmacology of TDI The few acute studies performed in anesthetized animals that have used reversible cold-block techniques to directly assess the effects of drugs acting as (ant)agonists of certain neurotransmitter substances have failed in identifying a putative neurotransmitter mediating TDI. For example, neither the inhibitory amino acids, glycine and GABA, the biogenic amines, NA and 5-HT [15, 50-52] nor endogenous opioids [16, 53-54] appear to mediate TDI. In fact, Soja and Sinclair [15] have demonstrated that intrinsic noradrenergic systems may actually oppose TDI in chloralose-anesthetized cats. Other work in anesthetized animals has shown indirect evidence that $GABA_B$ and/or $5\text{-}HT_{1A/3}$ receptors may partly mediate TDI of unidentified, but nevertheless functionally characterized, dorsal horn neurons [55-60]. However, these studies did not measure TDI before and after drug administration. Clearly no consistent picture emerges here. New studies designed to verify of TDI's existence on STT neurons as a real physiological mechanism in the intact animal without surgery and anesthetic-induced distortion are critical for elucidating its origin and neurotransmitter basis.

Tonic Descending Facilitation (TDF) The majority of investigators who have documented TDI on lumbar sensory interneurons have reported on a minority of recorded cells whose spontaneous discharge rate and peripherally-evoked responses are markedly suppressed during the cold-blocked state of the spinal cord relative to the normal state of the cord [6, 16, 31, 61-63] suggesting the existence of tonic descending facilitation (TDF). Virtually nothing is known regarding the cellular mechanism (*i.e.*, disinhibition *vs.* postsynaptic excitation), underlying synaptic circuitry, pharmacology, and/or function of TDF.

Summary & Conclusions As reviewed above, TDI is a complex phenomenon whose biological significance remains to be determined. We report in these proceedings, that the nature of tonic

descending influences, *i.e.*, inhibition or facilitation, affecting STT neurons *actually depends on which anesthetic is used to maintain the state of unconsciousness.* These findings will have major implications to current concepts of TDI controlling spinal neurons comprising classical sensory tracts, namely the STT, as well as the importance of experimental design, including critical drug-free controls, when assessing descending controls from the higher brain under natural conditions.

Introduction

Neuropathic pain is a debilitating condition which has a serious impact on the quality of life in patients. It is a devastating and difficult-to-manage consequence of injury to the peripheral or central nervous system (PNS or CNS), which shows an enhanced transmission of pain messages [1]. Two cannabinoid receptor subtypes have been identified: cannabinoid receptor 1 (CB1), which is localized preferentially in several brain areas (PAG, cerebellum, hippocampus, cortex), and CB2, which are mainly expressed in peripheral tissue and in several inflammatory cells [2, 3]. Despite the general opinion which had up until recently believed CB2 receptors to be exclusively expressed in peripheral tissues, there is now convincing evidence to suggest that it is also expressed in the CNS. Indeed their increased expression in microglial cells as well as in astrocytes in neuropathic pain conditions has been shown [4, 5]. Microglial cells are the primary immunocompetent cell type within the CNS, serving a major role in the immune response to tissue injury or infection and subsequent removal of cellular debris [6]. Several studies have focused on the activation of spinal microglia in the pathogenesis of neuropathic pain [7, 8]. Here, we have evaluated the analgesic properties of a novel compound, 1-(2',4'-dichlorophenyl)-6-methyl-N-cyclohexylamine-1,4-dihydroindeno[1,2-c]pyrazole-3 carboxamide (NESS400), corresponding to compound 2a of the derivative series, whose pharmacokinetic and pharmacodynamic profile has been investigated in details [9]. Behavioural, biomolecular and immunohistochemical approaches have been used in order to investigate the effect of prolonged treatment with NESS400 in a model of neuropathic pain in mice on i) pain threshold, ii) glial and microglial activation, iii) pro/anti-inflammatory cytokine expression in the spinal cord.

Material and Methods

Animals

Male C57BL/6N mice (35-40 g) were housed 3 per cage under controlled illumination (12:12 h light:dark cycle; light on 06.00 h) and environmental conditions (room temperature 20-22° C, humidity 55-60%) for at least 1 week before the commencement of experiments.

Spared nerve injury

Mononeuropathy was induced according to the method of Decostered and Woolf [10]. Mice were anaesthetised with sodium pentobarbital (50 mg/kg, i.p.).

Pain behaviour

Thermal hyperalgesia was evaluated by using the Plantar Test Apparatus. After a 30 min habituation period, the plantar surface of the hind paw was exposed to a beam of radiant heat through the glass floor. Mechanical allodynia was measured by using the Dynamic Plantar Aesthesiometer. Nociceptive responses for thermal and mechanical sensitivity were measured in seconds and grams, respectively. Baseline thresholds were determined 6 days before starting the treatments.

Immunohistochemistry

Transverse sections (20 □m) were cut using a cryostat and thaw-mounted onto glass slides. Slides

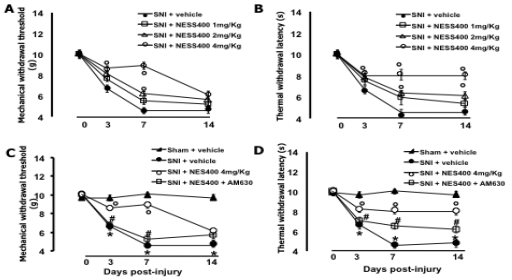
were incubated primary antibody solutions for the marker Iba-1, or anti-Glial Fibrillary Acid Protein or CB2 receptor or anti-interleukin 1ß**.** Following incubation, sections were washed and incubated with secondary antibody solution.

Results

NESS400 reduced thermal hyperalgesia and mechanical allodynia in mice with SNI

Chronic administration of NESS400 (4 mg kg^{-1}, i.p.) from day 1 to day 14 reduced mechanical hypersensitivity at 3 and 7 but not at 14 days after nerve injury (Fig.1 A,C). However, thermal hyperalgesia was prevented by NESS400 from day 3 to day 14 (Fig. 1B,D). The anti-allodynic and anti-hyperalgesic effects of NESS400 were prevented by concomitant treatment with the CB2 receptor antagonist, AM630 (1 mg kg^{-1},i.p.) (Fig. 1, A,B).

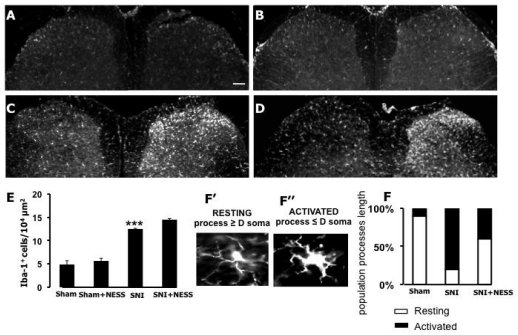
Fig.1



NESS400-induced analgesia is associated with a reduction of microglial and astrocyte activation 7 days after SNI induction

NESS400 chronic treatment did not decrease the number of Iba-1 positive profiles which were increased in the ipsilateral dorsal horn of spinal cord 7 days post-SNI. However the number of the activated microglia, defined as the cells showing the diameter of the soma > than the length of the processes, was decreased by NESS400 treatment (Fig.2).

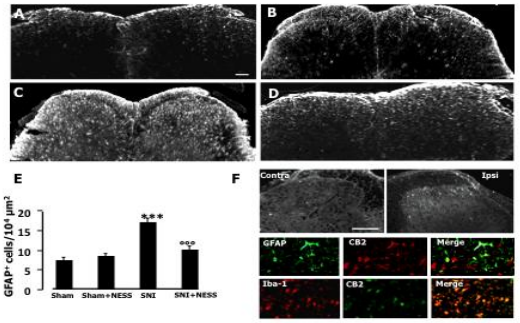
Fig.2



The number of astrocytes, as identified by GFAP staining, was strongly up-regulated 7 days after the induction of SNI in the ipsilateral dorsal horn as compared to sham mice (Fig. 3 C, E). Chronic treatment with NESS400 significantly reduced the number of GFAP positive profiles as compared to SNI-vehicle treated animals (Fig. 3 D, E).

In order to provide a cellular site of action for NESS400, we subsequently investigated the presence of CB2 receptor in the dorsal horn.

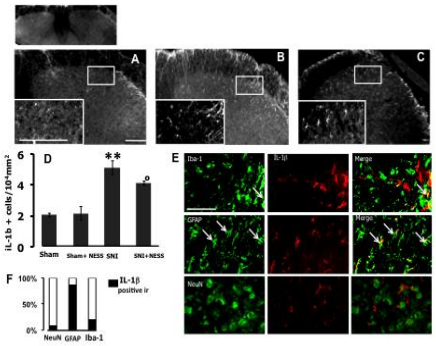
Fig.4



NESS400 treatment is associated with IL-1β reduction 7 days after SNI induction

IL-1β was over-expressed 7 days post-SNI mostly in spinal astrocytes as revealed by double labelling with GFAP. Also microglial cells expressed IL-1β although in a lower percentage (Fig.4)

Fig.4



Discussion

In this study we show that chronic treatment with NESS400, a novel compound which has been characterized *in vitro* as a selective CB2 receptor agonist (Murineddu *et al*., 2006), reduced mechanical allodynia and thermal hyperalgesia in a mouse model of neuropathic pain. The same treatment reduced microglial hypertrophic state in the ipsilateral dorsal horn of the spinal cord to the nerve injury. Intriguingly, the total number of microglial cells was increased by NESS400 thereby suggesting that this CB2 agonist induces cell proliferation. Astrocyte up-regulation was also decreased by NESS400 chronic treatment. The site of action of NESS400 is likely to be the CB2R which we found up-regulated mostly in activated microglia, but also in astrocytes following peripheral nerve injury. Beside the effect of microglial action of the NESS400, we cannot exclude any peripheral mechanism since we administrated the drug systemically. Thus, in the puzzling network at the base of neurodegenerative processes associated with neuropathic pain establishment and maintenance, CB2 receptor is a great candidate to target although further investigation is required in order to identify the contribution of supraspinal and spinal CB2 receptors within the CNS in pain control.

THE PALMITOYLETHANOLAMIDE: AN IMPORTANT TOOL FOR PAIN MANAGEMENT.

Calignano Antonio
Department of Experimental Pharmacology, University of Naples, Naples 80139, Italy

Palmitoylethanolamide (PEA), the naturally occurring amide of ethanolamine and palmitic acid, is an endogenous lipid that modulates pain and inflammation. Although the anti-inflammatory effects of PEA were first characterized nearly 50 years ago, the identity of the receptor mediating these actions has long remained elusive.
Here we outline the history of PEA, starting with its initial discovery in the 1950s, and discuss the pharmacological properties of this compound, and its mechanisms of action in which the nuclear receptor PPAR-alpha (peroxisome proliferator-activated receptor-alpha) play a crucial role in suppressing pain behaviors , nerve damage, and inflammation. The discovery that PPAR-a mediates the anti-inflammatory effects of PEA raises several important questions. How does endogenous PEA interact with PPAR-a to regulate physiological inflammatory processes.and non-cannabinoid FAEs, such as stearoylethanolamide also activate PPAR-a or related transcription factors. As these questions are progressively answered, we may not only gain insights on the PEA signaling system, but also identify new potential targets for analgesic and anti-inflammatory medicines
